Albuminuric retinitis really shows manifestations of edema of the retina, inflammatory changes being slight and secondary. Probably all the intraocular tissues share in the edema. Nutrition of the retina is disturbed, cells undergo fatty degeneration, cysts may form, and later lime salts may be deposited. The ophthalmoscopic appearances depend largely upon site of edema; if in the deeper layers, there are white, irregular patches in posterior pole of the eye; if in the nerve fibers near macula, star-shaped figures are produced. Edge of disc is blurred and the disc is swollen. A few small hemorrhages in the nerve fiber layer may be found. Choked disc, secondary to intracranial pressure, simulates albuminuric retinitis; but in the latter swelling of the disc is not so great and the veins are not so dilated. Albuminuric retinitis may occur in acute nephritis, albuminuria of pregnancy, and chronic tubular nephritis, but is most frequent clinically in cases of contracting granular kidney with a subacute nephritis developed on top of the chronic lesion. Arteriosclerotic appearances, therefore, frequently accompany retinitis. The prognosis in all cases of albuminuric retinitis is absolutely bad, not only as to recovery, but also as regards life. Death generally occurs in the course of a few months, except in the albuminuria of pregnancy. The eye symptoms are frequently the first brought to the attention of the physician in cases of nephritis, though it must be inferred that the disease is already far advanced by the time retinitis has developed.—*Australian Medical Journal*, July 29, 1911.

A New Reagent for the Detection and Estimation of Glucose in the Urine.—S. R. Benedict notes the defects of the usual tests for glucose in the urine. He shows that the presence of a strong alkali in Fehling's solution may under certain circumstances interfere with its power to demonstrate small quantities of sugar, and that urine contains compounds, chiefly creatinin, which seriously interfere with the detection of glucose. While a solution containing copper sulphate, Rochelle salts, and sodium carbonate is more than ten times as delicate a test as is Fehling's solution, and also more specific, not being reduced by the non-carbohydrate substances which readily reduce copper in the presence of the stronger alkali, it rapidly deteriorates. The author offers a formula for a solution which contains sodium or potassium citrate instead of Rochelle salts, which solution is free from this disadvantage and is not appreciably reduced by creatinin, uric acid, chloroform, or the simple aldehydes. It can be kept indefinitely in uncolored glass or cork-stoppered bottles. The formula is as follows: Copper sulphate (pure crystalized), 17.3 grams; sodium or potassium citrate, 173.0 grams; sodium carbonate (crystallized), 200.0 grams; one-half the weight of the anhydrous salt may be used; distilled water to make 1,000.0 c.c. The citrate and carbonate are dissolved together (with the aid of heat) in about 700 c.c. of water. The mixture is then poured (through a filter if necessary) into a larger beaker or casserole. The copper sulphate (which should be dissolved separately in about 100 c.c. of water) is then poured into the first solution, with constant stirring. The mixture is then cooled and diluted to 1 liter. By modifying the composition of the solution, it can be applied to the accurate and rapid quantitative estimation of sugar in urine. In this method, instead of the reduced copper being precipitated as the red suboxide which obscures the end-point of the reaction, it is precipitated as cuprous sulphocyanate, a snowwhite compound which rather aids the accurate observation of the disappearance of the last trace of blue color. In addition to the substances contained in the above-given solution, the solution for quantitative determination contains potassium sulphocyanate and a small amount of 5 per cent. potassium ferrocyanate solution. The amounts of the ingredients in the former solution are also slightly raised.—*Journal of the American Medical Association*, October 7, 1911.

Book Reviews.

Handbook of Suggestive Therapeutics, Applied Hypnotism, Psychic Science. A Manual of Practical Psychotherapy designed especially for the General Practitioner of Medicine and Surgery. By Henry S. Munro, M.D., Omaha, Neb. Third Edition, Revised and Enlarged. Price $4.00. St. Louis: C. V. Mosby Company, 1911.

The appearance of a third edition of a book on suggestive therapy by an American author within two years certainly indicates an awakened American interest in the subject. This author is not disposed to be conservative respecting the field of application of psychotherapy. He states that he finds "its greatest field of usefulness in the general practice of medicine in all classes of medical and surgical practice." In this he boldly takes issue with the neurologist and psychiater who are inclined to limit its field of application to conditions which come within the sphere of their own specialties. The author explains the application of suggestion, both with and without hypnotism, and illustrates his explanations with clinical cases from his own experience. His book is intended for the general practitioner. The present edition contains a number of added chapters. The fundamental principles underlying the psychoanalytic methods of psychotherapy are stated in the new edition. He finds the Freud method of "small value." The book is written in an interesting and entertaining style, and much of the new matter deals with mental training and hygiene.

La Neurasthénie Rurale. Frequence, Causes sociales et individuelles. Étude psychologique et clinique de la neurasthénie chez le Paysan contemporain. Par le Dr. Raymond Belbèze (de Nevers). Préface de M. le Professeur Rémond (de Metz). Price 3.50 francs. Paris: Vigot Frères, 1911.

This interesting little book treats exclusively, as stated in the title, of neurasthenia among those resident in rural districts. The author draws his conclusions from a study of 200 cases found in the peasantry of a certain region of France. About 30 per cent. of patients in eight years' practice in five small communities were classed by the author as neurasthenics. Isolation, economic conditions, intermarriage, autotoxemia, and intemperance were found to be frequent causes. Mental symptoms predominated. Some cases may have been charitably kept within the border line of insanity which others would place beyond that shadowy line. A chapter is devoted to neurasthenia in women and children. The general types of "rural neurasthenia" are divided into sexual, traumatic, melancholic, and paranoid. The chapter on treatment embraces some apparently original views on prophylaxis, interesting from a sociologic and psychologic standpoint. Some of the conditions existing in France mentioned under etiology, such as obligatory military service, fortunately, do not prevail in this country. The book commends itself to the country practitioner, but may be read with profit by the consultant.

Traité International de Psychologie Pathologique. Directeur: Dr. A. Marie. Tome deuxième, Psychopathologie clinique, par MM. les Professeurs Bagenoff, Bechterew, Drs. Colin, Capgras, Deny, Hesnard, Lhermitte, Magnan, A. Marie, Professeurs Pick, Pilcz, Régis, Drs. Riche, Roubinovitch, Serieux, Sollier, Professeur Ziehen. Avec 341 gravures dans le texte. 25 francs. Paris: Félix Alcan, Éditeur, 1911.

The first volume of this important work treated of General Psychopathology. It appeared last year, and has been reviewed in these columns. There is a similar collaboration of eminent neurologists and psychiaters (exclusive of the Kraepelin school, and especially representative of France, Germany, and Russia) in the preparation of the present volume, which is devoted to Clinical Psychopathology. The third volume, which will complete the work, is promised by the publishers the present year. Among the most important chapters of the present volume are the first one on the neuroses and psychoneuroses begun by Raymond, who has recently died; and the chapter on dementia paralytica by A. Marie and Dr. Lhermitte. Von Bechterew also gives an extremely interesting and valuable chapter on the psychic conditions accompanying organic diseases of the brain and other parts of the nervous system. Ziehen, Pick, Sollier, and others are assigned to the dementias and states of arrested brain development. Pilcz, Régis, Bagenoff, and others discuss circular and confusional forms of insanity; Magnan, Serieux, and Capgras the paranoias. The classification is a sort of compromise with the French. The descriptions are authoritative. The book is a useful one for reference.

The Refraction of the Eye: A Manual for Students. By Gustavus Hartridge, F.R.C.S., Consulting Surgeon to the Royal Westminster Hospital, etc. With 110 illustrations. Fifteenth Edition. Price $1.50. Philadelphia: P. Blakiston's Son & Co., 1911.

The fact that this work has reached the fifteenth edition is abundant evidence of its excellence and popularity with medical students. The volume is one of 275 pages, is well printed and well illustrated. The whole subject of refraction is taken up in logical order and treated in a simple, direct manner. The formulæ employed are not abstruse. The work is reliable. It is well adapted for the use of undergraduates in medicine and for the purpose of giving practitioners a working knowledge of refraction.

Die Pathologie des Wachstums im Säuglingsalter. In Ihren Beziehungen zu allgemein biologischen Problemen und in ihrer Bedeutung für die Klinik. Von Dr. Ernst Schloss. Mit 39 Kurven im Text und 2 Tafeln. Berlin: S. Karger, 1911.

The normal and pathological phenomena of growth in infancy comprise an unexplored territory in the domain of pediatrics. In this monograph of 155 pages the author presents a philosophical and experimental study of the morbid manifestations of growth, so far as these are related to biological problems and to the experiences of the clinic. In the first chapter he discusses the significance of nutrition with reference to the pathology of growth. In the second chapter are described the clinical manifestations of pathological growth, while in the third chapter is discussed the general pathology of growth in infancy. In the fourth and last chapter is discussed the significance of the pathology of growth in pediatrics. The work is a learned study of a most fundamental subject.

Thérapeutique Usuelle du Praticien. Par Albert Robin, Professor de clinique Thérapeutique à la Faculté de Médecine de Paris; Membre de l'Académie de Médecine. Deuxième Série. Price 8 francs. Paris: Vigot Frères, 1911.

This work forms the second series of the treatise on clinical therapeutics as presented in the practical course by the author at the Hôpital Beaujon of Paris. This series comprises 26 lessons, presenting a practical discussion of the mode of management of concrete cases, all theoretical considerations that have no direct bearing on the treatment of the particular patient being set aside. In this volume are discussed the following diseases: typhoid fever, erysipelas, acute articular rheumatism, and gonorrheal rheumatism; arthritis deformans, acute and chronic gout, diabetes mellitus, and diabetic albuminuria; pneumonia, acute edema of the lungs, pleurisy with effusion, diffuse bronchitis, and pulmonary emphysema; paresis, cerebral syphilis, paralysis agitans; and prurigo. Every little detail in the treatment together with its rationale is discussed: the drugs and their mode of administration, the hygienic measures, the use of mineral water, and physicotherapeutic measures. The author in writing this "practitioner's therapeutics" displays a keen appreciation of the everyday problems of the bedside as they are presented to the general practitioner. The typography and paper of this volume are of an unusual degree of excellence.

Wassermann Sero-Diagnosis of Syphilis in Its Application to Psychiatry. By Felix Plaut, Scientific Assistant in the Psychiatric Clinic of the University of Munich. Authorized Translation by Smith Ely Jelliffe, M.D., Ph.D., Professor of Psychiatry Fordham University, New York, and Louis Casamajor, A.M., M.D., Assistant, New York Neurological Institute. Price $2.00. New York: The Journal of Nervous and Mental Disease Publishing Company, 1911.

The author of this monograph, Plaut, is a pupil of Wassermann. His book is intended, he states in his preface, to give a short survey of the historical development of the Wassermann method and the diagnostic opportunities that have been afforded for the serodiagnosis of syphilis in the application of the method at the Psychiatric Clinic of the University of Munich, especially in the field of psychiatry. The phenomenon of complement fixation is a biological reaction the nature of which is still undetermined. Its application in practice, however, is but little contested because of the definite results obtained. Its application in the field of psychiatry is important on account of the relationship of syphilis to some forms of insanity, particularly to general paresis, of which it is a cause in men in more than three-fourths of all cases; and in conditions of idiocy and feeblemindedness where syphilis is often found present by the serodiagnosis test when all external appearances are healthy.

Manual of Psychiatry. By J. Rogues de Fursac, M.D., formerly Chief of Clinic at the Medical Faculty of Paris; Physician-in-Chief of the Public Insane Asylums of the Seine Department. Translated and Edited by A. J. Rosanoff, M.D., Second Assistant King's Park State Hospital, New York. Third American from the Third French Edition. Revised and Enlarged. Price $2.50. New York: John Wiley & Sons; London: Chapman & Hall, Limited.

Some revision has been made and considerable new matter added to the third edition of this convenient little manual of modern psychiatry. The volume is increased in size by about eighty pages. The author has added sections on disorders of writing; on acute mental attacks in the feeble minded; and on prognosis. The editor has contributed a description of some of the newer views in the progress of psychiatry, and the book is therefore made more valuable and up-to-date. The Kraepelin classification is followed, as in the previous editions. The references to original sources in connection with new matter will be appreciated.

A Manual of Pathology and Morbid Anatomy. By T. Henry Green, M.D., F.R.C.P., Consulting Physician to Charing Cross Hospital and to the Brompton Hospital for Consumption and Diseases of the Chest. Eleventh Edition, Revised and Enlarged by W. Cecil Bosanquet, M.A., M.D. (Oxon.), F.R.C.P. (Lond.), Assistant Physician (late pathologist) to Charing Cross Hospital and to the Brompton Hospital for Consumption and Diseases of the Chest; formerly Fellow of New College, Oxford. With 350 illustrations. Price $4.50 net. Philadelphia and New York: Lea & Febiger, 1911.

A good deal has been done in this eleventh edition of Green's Pathology to make it more useful for the student, for whom the book is designed. A considerable number of new cuts have been added and a good many changes have been introduced into the text to bring it more accurately into line with recent investigations. Within its limitations as an elementary textbook of pathology and bacteriology it cannot but prove satisfactory.

Pathological Technique. A Practical Manual for Workers in Pathological Histology and Bacteriology, including Directions for the Performance of Autopsies and for Clinical Diagnosis by Laboratory Methods. By Frank Burr Mallory, A.M., M.D., Associate Professor of Pathology Harvard University Medical School, Pathologist to the Boston City Hospital; and James Homer Wright, A.M., M.D., S.D., Director of the Pathological Laboratory of the Massachusetts General Hospital, Assistant Professor of Pathology Harvard University Medical School. Fifth Edition, Revised and Enlarged, with 162 illustrations. Price $3.00. Philadelphia and London: W. B. Saunders Company, 1911.

The high esteem in which this volume on laboratory technique is held by all laboratory workers is clearly shown by the appearance of the fifth edition. The additions to the text are chiefly in the methods of clinical pathology, though the portion on the bacteriological diagnosis of Asiatic cholera has undergone a timely revision. The various forms of serum tests for syphilis have been added, as well as special staining methods, including the use of India ink, for demonstrating the *Spirochæta pallida*. The admirable photomicrographs are still a striking feature of the book, which may be safely commended as the most practical of the purely technical guides for use in pathological laboratories.

The Prevention of Malaria. By Ronald Ross, D.P.H., F.R.C.S., D.Sc., LL.D., F.R.S., C.B., Nobel Laureate. With contributions by Professor L. O. Howard, United States; Colonel W. C. Gorgas, Panama; Mr. J. A. Le Prince, Panama; Sir R. Boyce, West Indies; Dr. W. T. Prout, Jamaica; Dr. H. Wolferstan Thomas, Amazon Region; Dr. Oswaldo Cruz, South Brazil; Dr. Ian Macdonald, Spain; Professor A. Celli, Italy; Professor C. Savas, Greece; Professor C. Schelling, German Possessions; Dr. Ed. Sergent, French Possessions; Mr. H. C. Ross, Egypt; Dr. A. Balfour, Khartum; Dr. L. Bostock, South Africa; Dr. P. Murisir, Durban; Dr. M. Watson, Malay States; Professor T. Takaki, Formosa; Colonel C. H. Melville, Troops in War; Major C. E. P. Fowler, Troops in Peace. With many illustrations. Price $5.00. New York: E. P. Dutton & Company, 1911.

As stated in the preface by the author of this work, "malaria is of all diseases the one regarding which we possess perhaps the fullest knowledge. We know the cause of it and the manner in which it is spread. We know a specific cure for it and several efficient methods of prevention. It is our own fault then if we do not reduce it as much as possible." The economic importance of this disease is indicated by the large and prolonged morbidity which it causes, particularly in tropical countries, in India alone the death rate from this disease reaching the annual total of 1,130,000 persons, a mortality greater than that of the plague or of cholera and dysentery combined. It is quite fitting that the writing of this book should have been undertaken by one whose scientific career has been so closely identified for many years with the progress of the knowledge of the causation of malaria, who indeed was the first to demonstrate that the anopheles is the actual carrier of the disease from man to man. In this connection Major Ross points out that in 1848 Dr. Josiah Nott, of Mobile, Ala., appears to have stated that both yellow fever and malaria may be transmitted by mosquitoes, and refers to the speculation as having been already advanced as regards malaria. The various steps that led up to the discovery of the transmission of the malarial organism, from the discovery of the plasmodium by Laveran to the demonstration of the mode of transmission by Ross, are described in detail. This volume does not take up the pathological and clinical aspects of malaria except in so far as these are related to the larger subject of prevention. Considerable stress is laid upon quantitative or enumerative ideas. The laws governing the diffusion of malaria in the community are elaborated with considerable mathematical detail. The "measurement of malaria" is considered from the viewpoint of the "parasite index," the "spleen index," the "fever index," the "constantly-sick index" and the variation of the malaria index according to age. It is concluded that the spleen index, obtained by palpation only, is by far the best method of measurement. The mortality and cost of malaria present startling figures. In Mauritius malaria produces one-half of the total mortality. L. O. Howard estimates that malaria costs the United States $100,000,000 a year. In the chapter on prevention the author discusses all those measures that have been found effective in preventing malaria, including screening, culicifuges, mosquito reduction, treatment, segregation, personal prophylaxis, selection of measures for public prevention, conduct of the campaign, directory, malaria survey, measures in schools, and cost of prevention. The campaign against malaria in the various countries is discussed in each case by an authority on this subject. The list of these authorities is indicated on the title page. Dr. Howard's description of anti-malarial work in the United States is particularly full. It is pleasing to note the merited credit accorded to Dr. Doty for the splendid manner in which he succeeded in practically exterminating the anopheles on Staten Island. Professor Angelo Celli's account of the campaign against malaria in Italy indicates the important part which this disease plays in the political measures of that country. The free distribution of quinine has apparently produced remarkable results; in seven years the annual consumption of State quinine has progressively increased from 2,242 to about 23,000 to 24,000 kilograms, and in the same period of time the mortality from malaria has progressively diminished four-fifths. Professor Savas of Athens describes the antimalarial work that has been accomplished in Greece, in which, from prehistoric times, malaria has been a greatly dreaded scourge. In 1905 Savas founded the Antimalarial League, which on the historic plain of Marathon worked out an object lesson with which to convince the nation of the efficacy of antimalarial measures. It is impossible within the narrow limits of this review to refer to many other interesting phases of this work, which should be on the reading shelf of every public health officer and student of sanitary science. The lay reader will find this book a most illuminating exposition of modern methods of organized medicine. The mature scholarship of the author, combined with his own practical experience, has enabled him to produce a truly monumental work.

Immune Sera. A Concise Exposition of the Main Parts and Theories of Infection and Immunity. By Charles Frederick Bolduan, Bacteriologist, Research Laboratory, Department of Health, City of New York. Fourth Edition, Rewritten and Enlarged. Price $1.50. New York: John Wiley & Sons; London: Chapman & Hall, Limited, 1911.

The title page adequately indicates the scope of this small volume, the demand for which and the rapid development of whose subject matter have necessitated the preparation of a fourth edition. The intricate phases of infection and immunity are simply and clearly presented by the author, who has included in the present edition all of the most recent contributions to this subject, such as the conglutination reaction, the Much-Holzmann cobra venom reaction, the meiostagnum reaction, Weil's cobra venom test in syphilis, and antitrypsin determinations.

Society Reports.

AMERICAN ASSOCIATION OF OBSTETRICIANS AND GYNECOLOGISTS.

Twenty-Fourth Annual Meeting, Held in Louisville, Ky., September 26, 27 and 28, 1911.

THE PRESIDENT, DR. HERMAN E. HAYD OF BUFFALO, N. Y., IN THE CHAIR.

THE meeting was held at the Seelbach Hotel, and addresses of welcome were delivered by Dr. Lewis S. McMurtry and the Mayor of Louisville, Hon. William O. Head. These were responded to by Dr. Charles N. Smith of Toledo.

Another Protest Against the Routine Use of Purgatives.—Dr. EDWIN WALKER of Evansville, Ind., stated that purgatives were used entirely too often by the profession and laity. Nearly all who consulted a physician used purgatives habitually. This routine use was vicious, and did much harm. This condition was due to their excessive use by the profession. A patient, when he first consulted a doctor, almost always received a laxative, and when he was dismissed he was directed to use it when necessary. All patients received a purgative before a surgical operation; this was a routine with practically all surgeons in and out of hospitals. Was it good practice to assume that every one who required a surgical operation likewise required a purge? If there was fecal accumulation it should present some symptoms. A large number of these patients had no disease or trouble with the alimentary canal. It was rare to find anything in the small intestine except in emergency operations soon after a full meal. If there was fecal retention, it was in the colon, and an enema was the better way to remove it. If there was fecal impaction, a simple purge would not remove it; several days at least would be necessary. The purgative increased the amount of fluid and also stimulated germ activity, which rendered the condition less favorable for an operation on the intestine or elsewhere. For seven years he had carefully recorded in all cases the habit in regard to purgatives, and he found over 90 per cent. of his cases used them habitually. Of this number all but a very small percentage were relieved of their constipation or other trouble as soon as the cathartics were withdrawn and regular habits and a suitable diet were adopted. The small number not thus relieved suffered from some trouble, organic or otherwise, which required treatment in which purgatives played a very small part. Careful study of cases with more accurate diagnosis would almost do away with the habitual use of laxative drugs. The purge after a surgical operation was needed in some cases to prevent accumulation in the rectum, which was not serious but caused some discomfort. Quietude and a limited diet were the causes of their failure to act, and when a liberal diet could be taken laxatives were rarely required. The purgatives could not remove infection. For local or general peritonitis following a laparotomy a purgative was contraindicated. Ochsner's treatment for appendicitis was applicable to these cases, as its aim was to inhibit peristalsis. Much had been written to emphasize this, but still physicians were purging these patients to their injury. When no infection existed, recovery, with the exception noted above, was better without a laxative. For seven years he had not given a purge for a surgical operation, except in rare cases, not 1 per cent. Patients were stronger and in a better condition for the ordeal. They had done better in every way, were more comfortable, and the abdominal cases had less pain and tympany. Gas pains were much less frequent. They had no complications which could be ascribed to the omission of the purge. The routine purgation of all surgical cases was absurd, was contrary to reason, and should be abandoned.

Dr. E. GUSTAV ZINKE of Cincinnati said it was his practice to take a daily scant teaspoonful of epsom salts. After this was taken the bowels acted naturally and satisfactorily in from fifteen to twenty minutes after breakfast. This must be associated with a mixed diet, solid food, and exercise, to keep the tone of the muscular structure of the colon in its natural condition. Diet and exercise, with a little saline every morning before breakfast, would answer in the vast majority of cases.

Dr. H. W. LONGYEAR of Detroit said there was one place where the protest of the essayist was certainly warranted, and that was, if one gave cathartics in cases of enteroptosis, it was extremely harmful. There was nothing more injurious than that, except the habit, perhaps, of prescribing very commonly cathartics in such cases without making a diagnosis. If the practitioner had a colon to deal with which was angulated and dropped down into the pelvis, if he gave the patient having that trouble cathartics, he was going to do him or her, as the case might be, a vast amount of harm. He was whipping the colon into an increasing action. It was like whipping a tired horse. He would get a little response from the whip, but the animal was injured. And so it was with the colon. If one constantly whipped it up with cathartics, he would make it worse and worse.

Dr. WILLIAM H. HUMISTON of Cleveland stated that a great many practitioners had been guilty of prescribing purgatives when they should not do so. A distinction should be made between a purgative and a laxative. A purgative was an irritating medicine always, while a laxative was not. He did not know how he could treat a number of cases that he saw that suffered from constipation asociated with the diseases peculiar to women without regularity of the bowels. There were women who came to the practitioner who did not have a bowel movement more than once in two or three days, or oftentimes only once a week. He did not give these patients purgatives, but he would dislike to continue the practice of his specialty unless he could avail himself of the benefits of what he called tonic laxatives. In the cases of long standing constipation that he saw, and with the form of tonic laxative he used, he was enabled within six weeks by constantly decreasing doses to establish the regularity of the bowels. After establishing regularity of the bowels, and the constipation had been apparently corrected, in examining these patients one might find disease of the pelvic organs, disease of the rectum, such as hemorrhoids and fissure, which he naturally saw when he treated cases of diseases peculiar to women. The form of tonic laxative he gave these patients was composed of cascara, strychnine, and aloin, in small doses, with a little ipecac, made up in pill form and gelatine coated. In his abdominal operations, where the patients were in the hospital, he had the bowels thoroughly cleaned out two days before operation by the administration of a dose of castor oil. A short time before the operation a high enema was given.

Dr. JOSEPH M. MATHEWS of Louisville thought that six-tenths of the people were constipated. If this was true, what were we going to do to unload their bowels? What harm could a purgative or laxative do if one gave it two days before an operation to unload the bowel of toxins or of fecal matter? It was known that every one had fecal matter in the colon, if not in the small bowel, and all one had to do to assure himself that this was true was to take a purgative and find out how much more he would pass after the administration of it than when he did not The bowel was the sewer of the body, and why not wash it out, and what harm did it do to wash it out? For a great many years he had given purgatives to patients

two or three days before operating on them to empty the bowel. He had given crab-orchard salts, as it surpassed all other salts, and it would do its work when epsom salts would not do so. He had for thirty years given these salts two or three days prior to operation, and sometimes it was surprising to note the amount of fecal matter a patient would pass. In many instances the condition of some of these patients who suffered from constipation was a surgical one, and oftentimes one was warranted, with Mr. Lane and Mr. Mummery, in removing the colon.

Dr. Hugo O. Pantzer of Indianapolis said he would not denounce the routine use of purgatives as strongly as did the essayist. It was the rectal retention of feces that did great harm.

Dr. Charles L. Bonifield of Cincinnati stated that it was necessary for the majority of people to have at least one evacuation of the bowels every twenty-four hours, and most people would be better off if they had more frequent evacuations. The essayist to some extent answered the question himself when he told how prevalent it was for the laity themselves to take laxatives. They used laxatives for the reason that they felt better after a free bowel movement. He had not succeeded very well in relieving many of these patients with a simple diet, but he had cured many of them by removing their hemorrhoids. A great many patients were constipated because the movement of the bowels was attended with more or less pain, and on account of this discomfort they put off going to stool as long as possible. In inflammatory conditions of the pelvis he knew of nothing except the prolonged use of hot douches that had so much tendency to deplete the congested pelvic organs as a free calomel purge, followed by a saline cathartic.

Dr. James F. Baldwin of Columbus said that when patients came to him with constipation as a marked symptom, he sent them to a professional friend who made diseases of the alimentary canal a specialty. He examined the stomach and alimentary canal in general and the stools, and gave enemata, douches, etc., and if after a few weeks or months he found he could not cure these patients, the speaker himself took them in hand and made a modification of the Lane operation, namely, switching the ileum from the beginning of the colon to the sigmoid, throwing it from one side to the other, as a man would throw a switch. He had had no deaths from this operation, and no morbidity, and the operation had given him in these bad cases excellent results.

Treatment of Sliding Hernia.—Dr. Walter C. G. Kirchner of St. Louis, after discussing the etiology, nature, and diagnosis of sliding hernia, described a method which he had employed in the treatment of these conditions. The principal steps of the operation were to convert immovable or adherent bowel into movable bowel; to make complete reduction possible; to construct the partial or incomplete sac into a normal complete sac; to permit ligation of the sac high up beyond the ring; to enable the complete repair of the hernia to be made by one of the typical and accepted operations for hernia. In his operation the sac, after it had been isolated, was incised on either side, near and parallel to the bowel, and in this way the bowel was provided with two lateral flaps of sac. The adherent bowel having been made movable beyond the ring, the sac flaps were turned back and sewed over the denuded area of bowel, and reposition of bowel into the abdominal cavity was thus made easy. The next step lay in the partial reconstruction of the sac so that ligation or suture at the neck as in normal cases was made possible. Of the fifteen cases of hernias operated on by the reconstruction of the sac and the flap method, ten were sliding hernias of the sigmoid, and five were sliding hernias of the cecum. All the cases occurred in adult male patients. In one case the sliding hernia was through the femoral ring, there being also present a right and left inguinal hernia. In eight cases there were double inguinal hernias, and in two instances these were complicated by femoral hernias. Undescended testicle was encountered once, and hydrocele four times. In the fifteen cases twenty-five separate herniotomies were performed, all the cases making a satisfactory recovery. In conclusion, the speaker emphasized the following points: (1) That a sliding hernia was irreducible by any of the nonoperable methods, and that a truss when worn might be harmful and painful. (2) That in these cases the usual surgical methods for treatment of hernia failed in their lasting results, and that recurrences were frequent. (3) That for success it was necessary to free the bowel so that it might be properly replaced, and to completely obliterate the sac. (4) That the method had proven successful, and that the steps of the procedure were applicable in the majority of cases, so that the method of repair might be considered typical.

Dr. John Young Brown of St. Louis said that his experience had been limited to five cases, and he had had the opportunity of seeing Dr. Kirchner operate in six or eight of his cases. In the cases that came under his observation the hernia had been on the right side. In three of them the cecum and appendix were densely adherent to the sac, making it difficult to liberate the adhesions, and he had found that the method adopted by the essayist of converting this complicated variety of hernia into a simple one, so that one could do the radical operation, had been of the greatest possible value to him. There was one thing in dealing with these hernias that must be carefully avoided. The sac was incomplete. In one of his cases, in endeavoring to open the sac, the bowel being detached behind, he came near getting into the bowel proper. This sliding variety of hernia was attached behind by the folds of mesentery, and by opening the sac in front, lifting up the bowel in the manner in which he had described, cutting the sac at right angles, one should see to it that the bowel was returned so that there would be no constriction of it at this point.

Angioma of the Uterus, Bladder and Broad Ligaments.—Dr. Hugo O. Pantzer of Indianapolis reported a case of racemose angioma of the uterus, bladder, urethra, and broad ligament. The patient was twenty-six years of age, married, and went through three pregnancies, two of which terminated at full term by forceps delivery. The cause of the dystocia was unknown. Both of the children were born dead. The third pregnancy terminated in the second month, probably owing to the angioma. This event was followed by grave hematuria and vesical tenesmus, excessive metrorrhagia, and menorrhagia. A fatal issue was averted by celiotomy and circumambient ligation. There was no more hematuria except a transient amount shortly after operating, provoked by exposure to cold and subsequent acute bronchitis and coughing. This attack of hematuria lasted two weeks, then it disappeared. Vesical irritability subsided gradually and permanently. Menstruation, which was at first profuse and prolonged, gradually became normal. One year and a half later the patient developed suppurative appendicitis. Operation revealed a recurrence of the angioma in the broad ligament external to the previous seat of the neoplasm. Ligation was again resorted to. Examination of the patient two years after the first operation revealed the nonpresence of angiomatous growth. There had been no return of the hematuria. The bladder was not irritable. Menstruation was normal. The general health of the patient was good.

Dr. Walter B. Dorsett of St. Louis said he had had two cases of angioma of the uterus in which he had taken out the organ, and he understood the essayist to say that he did not remove the uterus in his case. If so, so much

the better, for this was an advance in surgery. In operating on these cases, in which there was a suspicion of angioma on account of hemorrhage, which was the greatest difficulty encountered, he thought the ligation of the vessels, ovarian and uterine, was best made by the *en masse* method; that is, to grasp the whole mass with a good strong forceps and ligate on the outside of the forceps. In one of his cases he atempted to ligate the ovarian artery, and the ligature slipped off and the ovarian artery slipped up under the peritoneum. He slit up the peritoneum, seized the bleeding artery, and secured it, but the woman had a sudden hemorrhage during the night, from which she died, so he believed that in the ligation of angiomas of the uterus, where there was an abnormal condition of the arteries themselves, it was best to ligate them *en masse,* and not only do so in that manner, but to sew in the suture after one had thoroughly tied it with a No. 2 catgut ligature.

Dr. John W. Poucher of Poughkeepsie said that in one of these cases, after an operation had been performed by a colleague from another city, he had the after-care of the patient, but unfortunately this patient—although there was no sign of hemorrhage at the time the angioma was ligated—suffered severely from a secondary hemorrhage, and the family insisted upon waiting for the operator to come from a distant city, and the patient died as the result of the secondary hemorrhage. If in all these cases one could be assured of not having a recurrent hemorrhage, the conservative method of operating was preferable.

Dr. Francis Reder of St. Louis said he had met with various angiomatous conditions of the uterus in connection with fibroid tumors, where it was necessary to ablate the organ. Sometimes one met with angioma in the broad ligament, or the pampiniform plexus. He knew that in these racemose angiomas there was destruction of the anterior uterine wall, and one would find a resisting organ of considerable density.

Dr. Charles L. Bonifield of Cincinnati agreed with Dr. Dorsett that it was best to ligate the ovarian arteries *en masse,* and during the report of this case it struck him that it might have been possible and would have made the operation easier had Dr. Pantzer by ligating the ovarian artery on the right side proceeded to have ligated the internal iliac artery, as was done in some cases of extensive cancer. In this way he would have controlled effectually the arterial supply of the tumor.

Congenital Multicystic Mucoid Tumor of the Small Intestine.—Dr. H. W. Longyear of Detroit said the tumor was about two inches in length, situated subperitoneally on the sides and mesenteric aspects of the small intestine, and was composed of an aggregation of small cysts, filled with mucus. The pathology in the case reported was discovered accidentally during an appendectomy, and the tumor was not removed, as it was apparently benign and causing no symptoms. It was thought by some to be allied to the gas cysts of the intestine, as reported by Finney and others, although differing materially in some respects. The etiology was obscure, but such tumors were probably congenital in origin, like dermoids, developing from foreign cells, accidentally misplaced *in embryo.* Their growth was slow and without symptoms, excepting where the lumen of the bowel might become occluded, and they required no treatment unless the symptoms of such condition were present, when a resection of the bowel containing the tumor was indicated.

Diseases of the Thyroid in the Female.—Dr. Miles F. Porter of Fort Wayne said the thyroid was of especial interest to the gynecologist and obstetrician. Women were five times more prone to thyroid disease than men. The thyroid was originally a sex organ. The thyroid was especially active during the period of sexual activity, and increased in size during menstruation and pregnancy. The toxemia of pregnancy and puerperal infections were probably often due to inactivity of the thyroid. Both clinical observation and post-mortem findings supported this statement. Goiter might be due to disease of the genital organs. Disease of the thyroid might cause amenorrhea, dysmenorrhea, menorrhagia, sterility, mental aberration, premature separation of the placenta, and chlorosis. Goiter in the mother often produced bone deformities in the offspring. He reported six cases occurring in his own practice, and cited facts supporting the above statements. Clinical investigations along the lines suggested promised an abundant harvest, and the object of his paper was to stimulate such investigation.

Dr. William D. Haggard of Nashville stated that only a few days ago, showing the relationship between the sexual function and the thyroid gland, he saw a woman with exophthalmic goiter, with very marked symptoms, and hyperthyroidism, who married last November, at the age of thirty, and in January had marked enlargement of the thyroid, with tachycardia, tremor, and a beginning exophthalmos. She conceived in February, and aborted in May. During her pregnancy her symptoms were considerably exaggerated, and an interesting feature was that these symptoms all subsided after the miscarriage. She still had a chronic hyperthyroidism which had recently become more active and for which he thought a partial thyroidectomy was necessary to afford relief. He was satisfied that there was a great undiscovered country in the ductless glands bearing upon their interrelation in the causation of some of our mysterious pathology.

Dr. Hugo O. Pantzer of Indianapolis recalled a case he had in his own practice two years ago. He removed a fibroid tumor of the uterus, doing a unilateral oothectomy in an individual who had at the time moderate Graves' disease. Within twenty-four hours after the operation this patient had a very conspicuous thyroid. At his visit the following morning he found that the thyroid had been as absolutely removed as though he had taken it off with a knife. Nine or ten days afterwards the patient developed bilateral trouble, and then had hyperthyreoidea in the worst degree from which she recovered only slowly within the next two months.

Dr. Albert Vander Veer of Albany had been impressed with the enlarged thyroid in connection with uterine fibroids, and recalled one case that he had under observation for some time. He removed a fibroid tumor from this woman ten years ago. She was thirty-one years of age then, she had a good-sized fibroid tumor, and she had a marked enlargement of the thyroid gland. Ten years later she came to him and said, "Doctor, I must be having the change of life." Her uterine appendages had been removed at the time with the fibroid, and she had gone along without any unpleasant symptoms up to this time. When she came to him, she had all the marked symptoms of goiter, with hot flashes, etc. On examining her he found that the thyroid gland was slightly enlarged. She presented many of the symptoms of exophthalmic goiter. Her case cleared up nicely under the use of the thyroid extract, but the cause of the condition and the therapeutic remedy given for it were not clear to his mind.

Dr. Edwin Walker of Evansville said that a number of years ago he had an experience along this line that made a deep impression upon him. The patient came from a highly neurotic family and had suffered from epilepsy during her early life. At about puberty these attacks became worse, and a good deal of the time the patient was in the condition of status epilepticus, having from forty to sixty attacks a day. Bromides had no effect whatever on these attacks. At that time he had a case of myxedema in a man who had his thyroid destroyed by suppuration, and as he had this subject in mind he noticed that there

were a few symptoms about this girl that suggested the possibility of hypothyroidism, although practically nothing could be found in the literature on the subject. She had puffiness of the face, she had a swelling of her hands, and stiffness which resembled that present in the other patient. He put her on the thyroid extract. He fed her on partially cooked thyroids, and her recovery was so remarkable and so rapid that it did not seem to him to be possible. Whenever he would stop the administration of this thyroid extract there would be a return of the symptoms. At about that time the thyroid extract was put on the market. He kept her on thyroid extract for a year or more. She had been under his observation since that time; she was fifteen years of age then, and thirty-five years of age now, and she had been entirely relieved of her epilepsy.

Dr. Roland E. Skeel of Cleveland stated that last year he saw a patient who was choking rapidly because of a rapid enlargement of the thyroid. The woman was eight months pregnant. She had an attack of dyspnea, and she had such a severe stridor that it could be heard across the corridor. She had an enormous thyroid which was removed under local anesthesia, and, being fearful she might be delivered of an eight months' child, he ordered a small dose of morphine. To his consternation, after giving the morphine, she had a very marked toxemia of pregnancy, so much so that the urine contained from 10 to 15 per cent. of albumin. This was contrary to what was observed under these circumstances. There was a rupture of the bulb of the jugular vein, and the woman died instantly. The house surgeon made a post-mortem cesarean section, and secured a living child. The child lived a few weeks, then died from ordinary marasmus. This case illustrated the risk the practitioner ran in drawing any definite conclusions with reference to the thyroid.

Dr. William H. Humiston of Cleveland said that gynecologists saw many cases in which there were a rapid pulse and a great many symptoms that they were at a loss to account for, and examination of the thyroid showed no enlargement whatsoever. His experience in these cases had been that with the administration of the thyroid extract he had universally obtained good results. He very rarely saw a failure after the administration of the thyroid extract.

Dr. Robert T. Morris of New York said that if there was a hypothyroidism the thyroid extract furnished a substance which was not furnished in sufficient quantity by the gland itself. If there was a hyperthyroidism, it often meant that there was a compensatory hypertrophy of the gland which was under great demand, and in that case if one gave the thyroid extract he lessened the need for compensatory hypertrophy on the part of the gland, so that in certain cases of hypothyroidism and in cases of hyperthyroidism one used precisely the same therapeutic resource because of the two different groups of cases, but each case in itself became a study. In one case one would find with the *x*-ray alone he could overcome almost all of the symptoms of hypo- or hyperthyroidism, in another case with the thyroid extract he was using, while in another case he had to use both together, and in still another case he would produce disastrous results with either one of the two. One could not at the present time anticipate precisely what the result was going to be from the use of the thyroid extract until he had a much more elaborate classification of these cases, and a statement of them in such a way that one might anticipate results.

Dr. Porter (closing the discussion) stated that it was not at all proven that a woman with Graves' disease was suffering from an overactive thyroid, but up to date this was our best working hypothesis. Here was a woman with a large goiter and she got better with the administration of the thyroid extract. He believed nine-tenths of these women would get better for the simple reason that an individual with a large goiter was not suffering from hyperthyroidism. It was the myxedemic patient, and not the hyperthyroid case, that suffered. The size of the thyroid cut no figure, and the patient might die from so-called Graves' diesease with no enlargement of the thyroid gland.

AMERICAN RONTGEN RAY SOCIETY.

Twelfth Annual Meeting, Held in Richmond, Va., September 20 to 23, 1911.

The President, Dr. Percy Brown of Boston, Mass., in the Chair.

Officers Elected.—The following officers were elected to serve for the ensuing year: *President*, Dr. Frederick H. Baetjer, Johns Hopkins University, Baltimore; *Vice-Presidents*, Drs. H. W. Van Allen, Springfield, Mass.; G. M. Steele, Oshkosh, Wis.; J. H. Edmondson, Birmingham, Ala.; W. H. Eagar, Halifax, N. S., and Hollis E. Potter, Chicago; *Secretary*, Dr. Henry K. Pancoast, University of Pennsylvania, Philadelphia; *Treasurer*, Dr. Charles F. Bowen, Columbus, Ohio; *Librarian*, Dr. H. W. Dachtler, Toledo, Ohio. *Executive Committee:* Drs. P. M. Hickey, Detroit; Arthur Holding, Albany, N. Y., and Alfred L. Gray, Richmond, Va.

Niagara Falls, N. Y., was selected as the place for holding the next annual meeting in September, 1912.

Röntgenology and Its Relation to the Law.—Dr. Percy Brown of Boston, Mass., said that the practice of röntgenology as a specialty of medicine and the practice of the law had been brought into contact on many occasions during the past fifteen years. This relationship had been distinctly of two kinds: one, where evidence of disease or injury, obtained by *x*-rays, has been made use of in court, and another, where, for alleged malpractice by improper or injudicial use of *x*-rays, certain medical practitioners had been made the defendants in processes of civil litigation. Of cases where legal proceedings had been engendered by the alleged misuse of *x*-rays, either as a diagnostic or therapeutic agent, it was a satisfaction to be able to say that occurrences were far fewer than formerly. This was no doubt due to the fact that through discouragement of one sort or another the clinical application of *x*-rays was being relinquished by many unqualified and incompetent persons. The earliest attempts, apparently, to introduce into court the results of examination by *x*-rays consisted of the presentation, for examination by the jury, of solar prints upon paper, from the original diagnostic plates. This procedure was ill-advised—at least it was an unfortunate thing to have evidence presented by a means so inaccurate, for prints were more or less naturally accepted by many courts as photographs, to come under the head of documentary evidence, and considered quite as any record produced with the photographic lens by solar illumination. This early attitude of the courts toward the character of evidence of this sort was shown in nearly every supreme court decision upon the subject to be obtained from the reports. It would be seen in almost every citation obtained from the records that evidence produced by means of the röntgen rays was regarded much in the same light as a solar photograph would be. Consequently it was considered of a nature documentary, and certain lawyers had even gone so far as to attempt on this ground to have it introduced as secondary evidence. A perusal of early judicial opinions, thus recorded upon the status of the *x*-rays in court, only tended to stimulate, through the very adversity of this opinion, the röntgenologist having any belief in the dignity of his position in medicine.

It stimulated him to set up for himself, and for his fellows, certain standards to which should be lifted not only his conduct in court, but the evidence which he offered. Inferences of distinct value to the good conduct of a case had been offered, in matters connected with *x*-rays, by witnesses who would have been quite unable to qualify as medical experts. The very fact that this question allowed of a direct and a converse interpretation suggested an element of confusion. Since they could duly qualify under the law as medical experts, many admirable physicians or surgeons believed themselves able to give expert opinion upon matters connected with the interpretation of *x*-ray records in court, and were on record as saying so. Let them under oath essay the not infrequent röntgenological problem (and, by the way, a possible very pretty legal problem as well) of the differential diagnosis between a tibial periostitis sustained traumatically in a railroad collision and the same lesion in the same place contracted as the result of a social misdemeanor, and their qualifications as medical experts might avail them little. In short, the qualifications of the röntgen worker as a medical expert witness should be themselves qualified. The court should not be content to accept him as a medical practitioner (which he invariably should be) alone, but his recognition in his own community and in a recognized society of his colleagues should be ascertained and testified to. The first standard to be set up should be proper professional qualifications. The röntgenologist as a medical expert in court held untold power to effect a good or bad impression by his manner of conduct. He could also by his testimony very easily alter many aspects of the case. An absolute neutral attitude, therefore, should ever place him absolutely beyond reproach. Consequently, just because he was armed with advantages far beyond those possessed by the average expert, he could well raise as his second standard "proper professional conduct." The very fact that he was empowered by means of his art to produce evidence from the realms of the unseen, which was ordinarily denied to the human eye, added additional dignity to that evidence and to the testimony of the one producing it in court. Since this was so, he could never overexert himself in the preparation of such evidence as he might have to present. It often happened that there was no suspicion of possible litigation at the time he made his original examination. This fact made it all the more necessary for him to apply to himself one of the fundamental essentials of the true röntgenologist, namely, attention to detail. Thus, whatever might be the ultimate outcome of any case, the careful worker should never be caught unawares whenever his services were sought by the courts. The employment of pains and care, however, the röntgenologist must be careful not to ovedo. The evidence of his zeal might be misappropriated. This caution applied especially to the marking of his records before the case came up for trial. Beyond a general mark for purposes of identification, such as his own case number or plate number, it were better that all records be marked in the presence of the court at the time they were admitted as evidence. It might be likewise argued that evidence by *x*-rays be ruled out on the ground that the examination was made at a period of time too remote from the time of injury to make the evidence competent. The röntgenologist might also have his evidence challenged on the ground that its presentation to the jury might tend to excite sympathy or prejudice. Unless his evidence could rest upon the framework of his professional qualifications as an expert (and qualifications much more drastic than those required by law), it would surely lose weight, if indeed it was not quite discredited through its own incompetence. As a röntgenologist one would naturally like to see all evidence bearing on physical examinations by *x*-rays exalted from the level of secondary documentary evidence to the plane of primary evidence of opinion. One would like to see röntgenologists removed from the gamut of the photographer on the witness stand, their statements received with disdain by our legal brethren, to that class of conservative rational expert witnesses whose statements suggested safety and sanity if nothing more. This would be accomplished just as soon as the legalized practice of röntgenology was given over to intelligent, cool-headed, and deep-thinking medical men, and taken from the hands of whirling dervishes.

Röntgen Ray in Hypertrophied Prostate.—Dr. James W. Hunter of Norfolk, Va., said the ideal treatment in hypertrophied prostate was radical removal of the gland. In the hands of expert operators who selected their cases the results were excellent; in the hands of the occasional operator or the inexpert the mortality was high. In selected cases röntgenotherapy was of great value. When the increase in size was due largely to overgrowth of the epithelium the röntgen ray would quickly diminish the size of the gland, but not so if there was much increase in the amount of connective tissue. The results from the treatment depended largely on the histological structure. Massage was indicated as an adjuvant. The mortality was *nil*.

Dr. Hollis E. Potter of Chicago thought it was not easy to differentiate by digital examination between a fibrous, muscular, or epithelial enlargement of the prostate; but by raying the testicles as well as the prostate one could produce an effect analogous to that produced by raying the ovaries and uterus, reducing the size of the gland considerably. He had, however, seen few good results follow the röntgen treatment of hypertrophied prostate.

Dr. George E. Pfahler of Philadelphia thought sufficiently good results had been obtained by careful workers to cause one to consider this treatment of hypertrophied prostate in otherwise hopeless cases and to justify its use. It was especially indicated in the case of old or decrepit patients, who could not stand an operation, and where the question of procreation was not to be considered.

Postoperative Röntgenization in Cancer.—Dr. Clarence E. Skinner of New Haven, Conn., said the widespread prevalence of such bitter antagonism toward *x*-ray therapy in cancer on the part of perfectly sincere and honest members of the surgical profession seemed to him to demonstrate that a grave duty to humanity imperatively confronted the members of the society, namely, the inauguration of an earnest, vigrous, and persistent campaign for the enlightenment of the lamentable ignorance which withheld from the cancer sufferer the beneficial potentialities of prompt postablative röntgenization. Cancer victims were going to continue to look to the surgeon for guidance in the management of their ailment, hence as long as he lingered under the burden of misapprehension, which was responsible for his present sceptical attitude, just so long would lives continue to be lost that might have been saved and suffering endured that might have been avoided. The potency of the *x*-ray influence over malignant processes once demonstrated, its prompt postablative employment, in every case, without waiting for recurrence, became a logical sequence. It was impossible to tell at the time of operation in which cases recurrence was going to take place; hence, in order to be sure that the cases which would need it would be treated, it was necessary to apply the measure to every case. Early recurrences were frequently internal, hence undiscoverable until such organs and tissues had been involved as to render absolutely useless the application of any remedy at present known. Many

recurrences were more vicious and resistant to röntgenization than the original lesion. When the *x*-ray had been thoroughly and skilfully applied immediately after the operation, it was known that everything had been done that offered the patient a chance of recovery. Postoperative röntgenization also rendered it possible to save some members of a class of cases which were hopeless under ablative treatment alone and usually hopeless under *x*-radiation alone, namely those in which the neoplasm had become so extensive that it could not be completely removed by the knife. He was aware that the *x*-ray alone would occasionally cure a case of this sort, but, as a rule, the *x*-ray alone would fail in such cases. By combining the knife and the ray, however, by first removing as much of the malignant tissue as possible and then röntgenizing immediately, not necessarily even waiting for the operation wound to heal in such a case, the cancer could sometimes be destroyed and the patient saved. The *x*-ray could frequently destroy small masses of cancer tissue when it could not destroy large masses, and initial extirpation of as much as possible of the growth reduced the amount of therapeutic work demanded of the ray. Some operators recommended that such cases should be rayed before operation, and the fact that reliable men reported good results from this method of administration showed that it had value, but he did not approve of it as a routine practice for the following reasons: First, the usual effect of vigorous *x*-radiation of a malignant growth was to produce a certain amount of systemic toxemia, which had been known to be severe enough to kill the patient of itself. Preoperative radiation was likely, therefore, to produce more or less depression of the vital powers, and it did not seem logical to him to invite systemic depression just before an operation. Second, radiation of parts containing malignant tissue caused fibrous tissue to take the place of the malignant tissue, and frequently resulted in such a fusion of tissues and obliteration of normal tissue distinctions and relations as to seriously embarrass the operation during the subsequent ablative procedure. Third, if the ray was capable of influencing the total original mass of such a growth happily, it would surely be capable of producing a much greater beneficial influence after the mass had been materially reduced in size by partial extirpation. Fourth, and to his mind the most important, effectual preoperative radiation meant delaying the operation for weeks, during which time the neoplasm was constantly threatening extension. It seemed to him distinctly inadvisable, to say the least, to subject the patient, by election, to such an ominous possibility.

Dr. George E. Pfahler of Philadelphia thought there was no doubt of the good effect of the röntgen ray in these cases. Unfortunately, the average surgeon would only refer those cases in which there was bound to be a recurrence and in which, therefore, little good could be effected. Anteoperative radiation was not advisable as a routine procedure, although he did not believe that it was as harmful as Dr. Skinner seemed to think. He had not seen any evidence of toxemia. However, postoperative treatment was certainly advisable and effective.

Dr. J. H. Edmondson of Birmingham, Ala., asked if it was not advisable to excise nodular recurrences in the scar before beginning the röntgen treatment.

Dr. W. H. Eagar of Halifax, N. S, said that one undoubtedly got a tremendous degree of toxemia from preoperative treatment, but early and effective radiation following operation was the proper thing. Unfortunately, these patients were not referred to us until after recurrences had appeared.

Dr. J. H. Selby of Rochester, Minn., believed that surgeons were becoming aware of the value of immediate postoperative röntgenization of these cases, because when the treatment was carried out by an expert who cooperated with the surgeon the results were always good.

Dr. Frederick H. Baetjer of Baltimore thought the preoperative treatment of these cases was criminal. The röntgen ray was stimulative and destructive, and any such form of treatment of a malignant process was wrong. One must not do anything to increase cell division because that increased the possibility of metastases occurring. A carcinoma that was operable was a surgical condition and not to be treated by the röntgen ray. So far as postoperative treatment was concerned, he agreed with the other speakers. He believed, however, that in many cases where enlarged glands were broken down by radiation these glands were not carcinomatous, but simply enlarged as the result of an inflammatory condition or reaction.

Carcinomatosis of Bones Secondary to Growth in Some Epithelial Organ.—Dr. Russell H. Boggs of Pittsburg said that carcinoma of the bone was always secondary. As a rule, it was not recognized until fracture occurred. It might be secondary to cancer, situated in any part of the body, and any bone might be involved, although it was usually a long bone. It was slow-growing and gave rise to symptoms which frequently led to a diagnosis of rheumatism.

Dr. Henry K. Pancoast of Philadelphia had one case in which a metastasis occurred in the femur just below the great trochanter eight years after the removal of a cancer of the breast. In another case a similar metastasis occurred following the removal of a bronchial cyst which had undergone carcinomatous degeneration. He had also seen metastases in the vertebræ.

Dr. George E. Pfahler of Philadelphia said that patients who complained of vague rheumatic pains after operations for the removal of malignant growths often were later found to be suffering from a bone metastasis, and unless fracture of the bone occurred the condition was not detected. A patient with recurrent carcinoma and metastases in the breast fell and broke his arm. He made a röntgenogram and found metastases not only in that arm, but in the other arm, and in one femur. Another patient fell and injured her hip. The röntgenogram showed distinctly a metastatic carcinoma, and on careful examination the original tumor was discovered in the breast, a small cancer, of whose existence the patient was not aware.

Dr. Frederick H. Baetjer of Baltimore had seen quite a number of cases of metastases of cancer in bone. Four of these were in the femur following a primary cancer of the breast. The femora and the spine were the most frequent seats of concerous metastases. He had had two cases of cancer of the humerus secondary to cancer of the stomach, and one case secondary to cancer of the bladder. In another case there were extensive metastases in the femur, and in the scapula secondary to the breast cancer.

Dr. George H. Stober of Denver had seen four cases of metastatic cancer of bones in which the primary tumor was situated in the breast. In one case the condition was not discovered until a fracture of the bone occurred twenty-five years after the removal of the breast cancer.

Dr. John H. Selby of Rochester, Minn., had seen a patient develop sciatica-like pains following the removal of a tumor of the kidney. He found complete destruction of the pubes, extending to the acetabulum. He had seen several cases of bone metastasis following cancer in distant parts of the body.

Duodenal Diagnosis: X-Ray Considerations, Describing a Technique for Fluoroscopy.—Dr. E. H. Skinner of Kansas City, Mo., said that they had been able to estimate a mechanical diagnosis of duodenal ulcer upon the following: When a bismuth and water suspension was

swallowed by a fasting patient, it readily passed the pylorous into the duodenum (because the acid stomach content was not taken up as when food was offered the stomach, neither was there a closure of pylorus as when a food bolus was swallowed). The stomach appeared normal after the ingestion of a bismuth meal (two ounces of bismuth oxychloride to thirteen ounces of cream of wheat porridge), but there was a vigorous peristalsis and a rapid emptying of the stomach in as short a time as one-half hour, and at least in two hours. The duodenum seemed to be sluggish and cast a shadow for a longer interval than usual, but the food rapidly traversed the remaining portion of the small intestines. By this method of filling the duodenum, as described above, the duodenum might present an hour-glass contraction at the site of the ulcer. Usually the duodenum was sluggish and did not exhibit any pronounced peristalsis. When the duodenum was filled and pressure was made at the outer curve of the duodenum, as shown by the shadow, the patient usually experienced some pain or discomfort. They placed the greatest weight upon the rapid emptying of a stomach that exhibited the usual normal J-shaped shadow and a vigorous peristalsis.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting Held October 6, 1911.

THE PRESIDENT, DR. WILLIAM M. POLK, IN THE CHAIR.

THE meeting was held under the auspices of the Section on Pediatrics.

The Secret Division of Fees.—The following resolution, voted by the Council, was read and it was voted unanimously that this resolution be endorsed by the Academy:

Resolved, That the secret division of a fee, or fees, with any person, or persons, who may be instrumental in influencing a patient, or patients, to apply for operative care or professional advice is unworthy of any member of the medical profession.

Resolved, That if such a division of fee is made by a member of The New York Academy of Medicine it should be counted as of sufficient ground for the expulsion of the member.

Resolved, That the Council considers it its duty to investigate charges against members made on the basis of such a division of fees, and on the receipt of proof of offense the Council may either permit the resignation of the person or expel him from the Academy.

The Influence of Milk Station Work on the Reduction of Infant Mortality.—Dr. GODFREY R. PISEK presented this paper, in which he described the work done by the milk stations in New York City during the past summer and of the results of this work. Cosmopolitan New York presented a problem in the reduction of infant mortality much more difficult than that presented by most other cities. There were 125,000 new-born babies every year in this city and it was felt that, if success could be demonstrated here, the movement would become state-wide and the appalling mortality revealed by the last census correspondingly reduced. The Committee for the Reduction of Infant Mortality had raised through voluntary contributions a quantity of money sufficient to establish 31 milk depots and had secured assistance toward the maintenance of 15 more stations under the control of the Department of Health. There were at the beginning of the summer 79 milk stations, including those of the Straus Laboratories, the Diet Kitchen, the Babies' Dairies, and two stations supported by the Nurses' Settlement and the Morningside Milk Dispensary. All of these agencies were associated for the purpose of eliminating wasted effort by confining the activities of each organization to a definite territory. The sum total of babies enrolled in these stations on the first of July was 5,932; by the end of the month there were 9,888; and at the end of August the enrollment was 11,702. Contrary to all expectation the enrollment continued to increase daily in spite of the fact that the warm weather was past. These stations dispensed 74,000 quarts of milk weekly. However, the milk station was no longer primarily designed merely for the distribution of milk, the education of the mothers had come to the front and the doctors and nurses were the more important factors. The intimate contact of the visiting nurses with the mothers allowed them to teach the mothers how to modify milk in their own homes according to the doctor's instructions presented according to the needs of the individual child. In these stations the whole milk with dilutions of simple gruels and the addition of ordinary granulated sugar was found to serve the purpose so well that this became the rule. The milk used was an excellent raw product and was preserved from deterioration in the homes by simple home-made ice boxes. The mothers were taught the value of breast milk and to recognize the danger signals of summer diarrhea and the necessity of immediate action. They were also instructed in the prenatal care of the infant. The writer felt convinced that many more lives had been saved than the statistics indicated. The children were strengthened so that there would be a lessened morbidity and they could better resist the encroachment of intercurrent diseases. Knowing that the work in New York City was being watched by cities all over the country they had decided to issue a weekly bulletin giving comparative statistics in infant mortality in the different cities. They had communicated with 355 health officers, 79 of whom expressed a willingness to give their statistics, while the others stated that their vital statistics were so imperfect that they would be of little value, thus showing the need for a national and State clearing house of information relating to infant mortality. The committee would continue their agitation on the subject of standardizing vital statistics with the hope that in another year comparative information might be made available. Statistics showed that the work of the summer had been effective. The number of deaths from all causes for the first nine months of the year was 11,733, while during the corresponding period of 1910 the number of deaths reached 12,920, or, in other words, a rate of 124.6 per one thousand infants this year against a rate of 142.3 for 1910, a decrease of 17.7 per one thousand infants. During the months of June, July, August, and September of this year there were 1,244 less deaths than during the corresponding period of 1910. There was a decrease of 1,417 deaths from the average of these four months for the past five years. In the Borough of Manhattan, from January 1 to June 1 there was an increase in the number of infant deaths of 28 per cent. over the corresponding period of 1910, but during the month of June, after the milk campaign was begun, there was a decrease in the mortality of 50 per cent. from that of last year. During July the decrease was 60 per cent., and the average for the whole summer was a decrease of 41 per cent. from the mortality of last year. A comparison of the results in New York City with those of other cities seemed to show that the diminished mortality was in direct relation to effective measures directed against the deaths of infants. In London, owing to hot weather, there was a sudden rise of infant mortality at the end of July from 173 to 304, and toward the end of August to 635 per 1,000 infants. To further prove the effectiveness of the campaign, comparative studies were made in different districts of the city. For instance two equally congested districts were taken for comparison. In one district having a milk station there were 419 deaths in 1910; in 1911 there were 298, a gain over last year of 29 per cent. In the other district, having no milk station, there were 302 deaths in 1910 and 333 in 1911, or an increase of 9 per cent. Dr. Pisek urged the members

of the profession to support the Health Commissioner in his attempt to get an appropriation sufficient to carry on the work throughout the year. If the work was kept up there would be less need of corrective work during school age, fewer inmates of our asylums and institutions, and a lessened burden on society.

The Principles of the Reduction of Infant Mortality, with Suggestions for Future Work.—Dr. S. Josephine Baker, Director of Child Hygiene of the Department of Health, read this paper. She stated that there was no other public health problem of the times, unless it might be that of tuberculosis, upon which they had so much absolute knowledge as upon that of the reduction of infant mortality. The problem of the reduction of infant mortality was an infinitely complex one having factors that might be classed as sanitary, hygienic, social, economic, humanitarian, philanthropic and individualistic. They must concede that no one line of endeavor, no matter how vigorously worked out, would permanently lower the infant death rate. Every beneficent feature must be used to its utmost worth and every undesirable one eliminated, and until this could be done they could only touch upon the high places, congratulating themselves one year upon achievement and deploring their lack of success the next. No greater danger could threaten their hope of ultimate victory than that of assuming that the total reduction of the death rate in any one year was wholly due to the specific efforts made during that year. The infant death rate of some years was lower than that of others irrespective of any efforts made to reduce it. From their present knowledge they could formulate one fundamental principle with certainty, namely, that prevention of disease must be their aim, and education their main weapon. That the educational work of recent years was beginning to bear fruit was shown by the fact that the reduction in infant mortality was constant over the entire country both in rural and urban districts notwithstanding the periods of heat which were more protracted and intense than for many previous years. If infant mortality was to be definitely and permanently lowered public opinion must be stimulated to demand that all civic forces be so adjusted and coordinated that the babies might be allowed to live, instead of forced into illness and doomed to death. Public opinion could insist upon better housing conditions, with sunlight and fresh air in living apartments, upon clean streets, adequate water supply, increased park space, playgrounds, recreation centers, the use of docks for the breezes from the waterfronts. Public opinion could place in the hands of the Health Department sufficient funds to carry out a widespread campaign for the instruction of mothers in the care of infants, and the provision of a sufficient number of milk stations to meet the needs of the infant population, and then it could uphold the wise expenditure of these funds with intelligent criticism and interest in results. Specifically the principles for the reduction of infant mortality included: 1. The study of the problem of the institution baby. During the present year up to October 1, 42 per cent. of all infant deaths in the Borough of Manhattan had occurred in institutions. 2. A supply of milk safe for infant feeding at a price within the reach of the majority of the people. Purification could not take the place of purity, but the matter was economic, and purity seemed beyond our reach at the price we could pay. 3. The broadening of the courses in pediatrics in the medical colleges so that they assumed the importance that was their due and assured every physician a thorough knowledge of infant hygiene and care. 4. The interest of social students and workers, and of philanthropists in meeting individual family needs and adjusting economic conditions. 5. The instruction of each mother in the necessity of nursing her baby, and if that was impossible then in the proper substitute feeding and how she might take advantage and apply the essential methods of hygienic baby care. 6. A right understanding of the immediate causes of infant mortality. These principles had been applied in part and a study of the thirty-year period from 1880 to 1910 demonstrating the changes in infant mortality was of interest. The death rate from contagious diseases in 1880 was 15.72 per one thousand; in 1910, 4.07 per one thousand; in 1880, the death rate from diarrheal diseases was 62.74; and in 1910, 39.71 per one thousand; the death rate from respiratory diseases in 1880 was 43.70; in 1910, 27.20 per one thousand; the death rate from congenital debility was 47.57 in 1880; in 1910 it was 45.68. The total death rate from all causes was 288.9 in 880 against 133.9 per one thousand in 1910, a reduction of 54 per cent. The number of deaths from diarrheal diseases from January 1 to October 1 was 3,227 or a death rate of 34.2 per thousand infants, as against 4,011 deaths, or a rate of 44.2 per one thousand infants, for the year 1910. They had never before had such a low death rate or such a systematic campaign in this city. The death rate among babies cared for by the milk stations was 2.5 per cent. of the entire number cared for. The nurses under the Department of Child Hygiene of the Department of Health had under their care 16,987 babies under one year of age from May 1 to September 10. Each baby was visited at least once in ten days; if ill or delicate more visits were made. One physician was assigned to each group of two or three nurses, and held daily consultations with them regarding the babies visited. All sick babies were cared for by the physicians and a record kept on file in each Borough office. The cost of this work amounted to about fifty cents a month for each baby. In addition the Department of Health held conferences for mothers and Little Mother's League, to teach older girls how to keep babies well. Dr. Baker said that she was convinced that they must put into effect a more comprehensive program for future achievement and suggested the following plan. 1. A more comprehensive and widespread campaign of educational publicity—one that would reach both the general public and the individual mothers. 2. The statistics cited showed that in that class described as congenital debility there had been practically no decline in the mortality rate during the past thirty years, thus making it evident their attention should be directed to this class. Here the obstetrician was needed; his control should not be limited to the confinement and the few succeeding weeks, but the mother should place herself under his control and follow his directions during the entire period of pregnancy. To this end they should have proper control of the midwives, classes for the supervision of pregnant women, a form of insurance that would provide a stated payment for a period of at least one month before and one month after the birth of a child, thus obviating the necessity for physical labor at this time, the cooperation of philanthropic forces and social workers to provide hygienic surroundings and freedom from anxiety for the mother during the prenatal period of the child's life. The question of institutional care versus the placing out system for foundling babies should be practically worked out. The death rate in institutions was abnormally high and all studies on the subject seemed to show that this rate was greatly reduced by boarding the children out in properly supervised homes. It was essential that they should recognize that infant mortality was an all year round proposition. The time to save the baby was before it got sick and not afterwards. Their educational campaign should be carried on in the winter as well as in the summer and their vigilance should never relax. Until this lesson was learned and provision made for persistent effort throughout the entire year they could never be wholly successful. Their present policy was shortsighted and expensive and utterly at variance with their present knowledge of preventive medicine.

Ernest J. Lederle, Ph. D., Commissioner of Health, said

that the Department of Health had asked the Board of Estimate for sufficient funds to carry on under permanent municipal auspices the work of the seventy milk stations that had been established in the City of New York, partly by the city and partly by the New York Milk Committee and other private organizations. During the last thirty years there had been remarkable changes in the control of the milk supply by the municipal authorities, especially by the Board of Health. Thirty years ago milk was adulterated by the removal of the cream, the addition of water, or both. About twelve years ago certain physicians became interested in infant feeding and it was found that there were often more important features to be considered in the milk supply that was used for infant feeding and the chief one was that the milk should be clean. The use of unclean milk meant injury to the infant. It was known that certain diseases were transmitted to infants as well as to adults through the agency of milk, and this pointed to a a new field of work. In 1902 and 1903 the Department of Health took upon itself the task of making bacteriological examinations to learn the condition of uncleanliness of the milk of the city, even going to the farms and creameries for this purpose. A system of inspection was established. Great results had been accomplished. At present they found, however, that they could not supply the quality of milk demanded, especially that required for infant feeding. It was impossible for the City of New York to use 1,600,000 quarts of milk a day that had been brought to the standard which would be proper for infant feeding; it was not, in fact, necessary that the whole supply of 1,600,000 quarts should be brought to this standard; it was not economic, nor was it proper to raise the cost of such a milk to a prohibitive degree. Therefore the Department of Health had decided to adopt an official grading of the city's milk supply into three classes as described in detail on a chart to which the Commissioner referred. There was Grade A for infants; Grade B for adults, and Grade C for cooking.

Dr. W. A. Evans, ex-Commissioner of Health of Chicago, said that one-third of the people of Chicago died from what were termed "bad air" diseases; one-third died from infant diseases; while the remaining one-third died from all the other things combined. It was, therefore, evident that this was a field of work that should be cleared up. From an economic standpoint it was worth while, for there was nothing in dead or neglected babies. In some communities it was very difficult to get people to understand the importance of this work. In the State of Mississippi there lived an old man who had not ben very well-to-do and he had a daughter named Sal, who always went barefooted. Once she was standing by the fire bare-footed, as usual, and with her eyes shut. Her mother said: "Sal, Sal, you got one bare foot on a red hot coal." Sal replied: "Which foot, ma?" This was similar to the attitude of the community toward the sick and dying child. He said that attitude should be changed.

Dr. Philip Van Ingen said he had made a study of infant mortality in the Borough of Manhattan for the last three years. In making comparisons up to the first of October, he found that in the Borough of Manhattan 33 per cent. of the decrease in infant mortality had occurred in 144 blocks immediately surrounding 11 milk stations. Of the total decrease in infant mortality in Manhattan, 33 per cent. occurred in an average of 13 blocks surrounding these stations. Since the work was begun by the Board of Health and other agencies, infant mortality had been on the decrease. There had been a decrease of 882 deaths among babies in four months in the Borough of Manhattan alone; there had been a total decrease of 1,811 in the Greater City of New York. Comparing the infant mortality since the founding of the milk stations with the previous years, or the average for the two previous years, they found a diminution of 29 per cent.; this showed that there was something at work. Their chief efforts were not directed toward the curing of sick babies, but keeping all infants well. The nurses went from house to house and talked with the mothers regarding their babies, urging them to make efforts to keep them well. This was an economical way of handling the proposition.

Dr. Henry Dwight Chapin called attention to the high mortality among infants in institutions; among a certain class of babies, the mortality would never be reduced so long as the babies were cared for in institutions. A large number of decrepit and underfed babies were not properly cared for at home; they drifted from place to place seeking relief and eventually died. Such a class of cases should be boarded out. Ten years ago he chose a certain district in the country where he had a doctor and nurse on salary and the babies were sent there to be boarded out. These were the atrophic, badly nourished infants. A large proportion of these had been saved. The city of New York should have districts near the city where such babies could be boarded out in small homes and receive a mother's care under the oversight of a doctor and nurse specially trained to handle sick infants. This would greatly reduce the death rate in this class of cases.

Dr. L. Emmett Holt said he was glad to hear Dr. Baker emphasize the fact that there was a high infant mortality all the year round. It was often forgotten that 25 per cent. of all infant deaths occurred during the first month of life and were due to congenital feebleness, prematurity, accidents of birth, etc., and were not influenced by the season of the year. The prevention of infant mortality should be begun by caring for the mother before the baby was born. The work of midwives should be carefully scrutinized; the newly born children should be followed up in the homes by the visiting nurse before they got sick. One of the most striking things to be noted in infant mortality in the past was the small number of deaths from gastrointestinal diseases among the well-to-do in contrast to what was seen among the poor. This was in part due to the difference in the milk supply, but largely to the care, instruction and attention which the well-to-do classes were able to command. Until very recently poor people had little opportunity to know what was proper in the care and feeding of children. Infant mortality was to be solved by methods of prevention, not therapeutics. Of all methods of prevention, education took first place. Dr. Holt strongly endorsed the application made by the Commissioner of Health to have the work now going on continued throughout the year.

Dr. William P. Northrup spoke of the importance of not treating these children in hospitals; his experience in attempting to cure them in hospitals was not encouraging. The follow-up nurse was of great value; she followed the mothers who brought their babies to the Out-Door Department and gave them instructions; the instructions were the most important part of her functions. The matter of education was the most important part of this subject. The doctor could not get far on the road of instruction without the aid of a follow-up nurse.

Dr. A. Jacobi said that the fact had been alluded to that a large number of cases died before the child was one week or one month old; they should not forget that. It was not a question of milk stations exclusively; it was a question of nursing from the very first. What could be done for the newly born baby should be done by the mother if she were capable. The mothers themselves, however, were not properly cared for. As a rule of 100 women, if properly fed and instructed, at least 95 were able to nurse their babies. These did not want milk stations; they had their milk stations in their own breasts. The mother should be cared for before the baby was born and particularly afterwards. There was no place in New York where these

poor women could go to rest up for six or eight weeks. There were now no more than 1,000 beds for any class of convalescents in the city of New York; they should have 10,000 beds. A number of private persons were now studying this question to learn what to do with these women after confinement. Now they were treated like acute patients in the hospital who were discharged as soon as the main symptoms of an acute disease had disappeared. Before considering what they should do for the babies, they should first do something for the women. If private persons would not do it, the community must do it. If a baby died, it was somebody's fault; if a baby died because of bad air or bad food, it was due to the community; the community should hold itself responsible. It was said that this was socialism. Dr. Jacobi said if this was so, the sooner they had it the better for the mothers and for the babies. He referred to the housing of these people. They must have good, pure air; not only should they have rest and good food, but they should get away from the foul air of the tenements. As an example they could not succeed in treating tuberculous patients unless they did that. The same with babies. They could not thrive in a badly ventilated and congested room. They would die of lack of fresh air and excess of heat. They would often die as people died from heat stroke. Heat stroke and bad air should be avoided. There should be better housing for the people, for the whole people, rich and poor.

Metabolism in Rheumatism; Food Factors in Rheumatism; Management of Valvular Lesions.—Dr. Joseph E. Winters said that he was thoroughly and absolutely convinced of the chemical etiology and chemical pathology of rheumatism. That contention was based on the products of protein metabolism; the irritant effects of these products existed when they were not neutralized by sufficient basic constituents in the food. The acid products of protien metabolism, when not neutralized by sufficient basic constituents, resulted in all the manifestations of rheumatism. The foul smell, the acid perspiration, the acid urine, etc., were phenomena never seen except in rheumatism, and for this toxic state the great laboratory of nature had provided a specific, namely, wintergreen which contained a large percentage of methyl salicylate, and which yielded salicylic acid. This was what destroyed the rheumatic element because it united with the acid. The end product of protein metabolism was invariably acid; the acid radical was always constant; protein contained basic constituents. Acids resulting from exogenous metabolism were immediately neutralized. Living molecules could not exist in an acid medium; the fluids in the tissues were rendered alkaline chiefly by the sodium compounds; the tissue cells chiefly by the potassium compounds. The mere trace of free acid menaced the alkaline medium. Acids were the foes of the body and they were distinctive of the disease rheumatism. Those who were susceptible or not susceptible to pathogenic bacteria as such were determined by the functional integrity of the enzymes. Salts that were to fulfil any important part in the life process must be taken into the body organically combined in the food. The mineral constituents that were not organically combined were useless. Beef tea, beef extract, bouillon, chicken broth and mutton broth were positive rheumatic factors; from these they got nitrogenous extractives, broken-down portein. Nitrogenous extractives excited excessive metabolism of the cell nuclei. The rheumatic factors were definite. The human body contained seven or more pounds of mineral matter and to provide ample salts in proper combinations in the food to neutralize the acid made it necessary to study with care the food. Lactic acid bacilli might convert 80 per cent. of the sugar into lactic acid. A large amount of water was necessary to dissolve the sugar for absorption; the result of this abstraction of water was delay, and this was followed by fermentation, and in this fermentation 50 per cent. of the sugar was converted into lactic acid. The lactic acid promptly withdrew alkalies from the tissues, and this was an important factor in the etiology of rheumatism. The natural history of rheumatism and chemical pathology were inseparable and interwoven. Acute rheumatism might continue for weeks and for months and the inflammatory causes were the same as they were on the first day; the disease might cease spontaneously and the joints would be found to be in as good a condition as they were before the disease began. The natural history of rheumatism had no parallel in diseases. The chemical pathology made it intelligible, understandable and clear.

Dr. Egbert Le Fevre said that he was sorry that time had not permitted Dr. Winters to differentiate between the types and conditions of so-called rheumatism based upon a chemical etiology and chemical pathology. He thought that all appreciated that as a result of the chemical changes mentioned by Dr. Winters there occurred arthritic conditions. Dr. Winters had not differentiated between the arthritic conditions which were undoubtedly due to faulty metabolism, that was, the gouty affections and acute articular rheumatism or rheumatic fever. From the brief presentation of his paper it was impossible to determine if he made a distinction. If he included the gouty conditions, then many of his premises and the conclusions based on them could be accepted. If, however, acute articular rheumatism was only considered, then many of his premises could not be accepted. That acute rheumatism was associated with hyperacidity of the secretions and other manifestations of acid intoxication he granted, but he was not willing to subscribe to the statement that it was dependent entirely upon metabolic changes resulting in the body from the want of a neutralizing base. He believed that the infectious nature of acute rheumatism must be considered. The very fact that the disease had pathological manifestations that were so definite, that the onset, the course, the termination and even the sequelae were so true to type, forced them to the conclusion that rheumatism was, in the majority of cases at least, an infective condition. The predisposing conditions in acute rheumatism, he believed, might be metabolic. Dr. Winters had struck an important point that they were very apt to overlook, namely, that improper food, especially in children, among other things so changed the resistance of the child that, during this vulnerable age, he was especially liable to infections. He believed in the infectious nature of rheumatism, although they had not as yet found the infectious agent. Dr. Le Fevre did not believe that rheumatism was due to a single infective agent; it might be due to a number as the streptococci, the pneumococci and influenza bacilli. He believed that they should consider acute rheumatism as an infectious disease. He was a strong believer in the efficacy of salicylic acid and its compounds, not only in its power to control the symptoms, but also to influence the sequelæ.

Dr. Harlow Brooks said that Dr. Winters had certainly presented the theory of the chemical or metabolic etiology of acute rheumatic fever in a most favorable light; a more logical argument in its favor could not be made; nevertheless, although "almost persuaded to believe" he could not relinquish his firm conviction that rheumatic fever should be grouped with the infections, and personally he believed that it was a mixed infection, not a pure one, for he did not believe that the contention of Poynton and Payne had been sufficiently supported by other workers. There were a few clinical facts not mentioned by Dr. Winters which tended to support the chemical theory; among them was the well-established observation that this disease existed for the greater part in localities and among subjects who were very resistant to most infections; also it was a disease notably of the vigorous and of the outdoor

liver, lumbermen, miners, prospectors, etc., all of whom suffered relatively but little from the ordinary infections. The well-established relationship between climatic and seasonal conditions, between dietetic and other predisposing factors and the occurrence of the disease might also be used as arguments in this direction. Taken as a whole, however, the clinical aspects of the disease certainly were those of an infection: its pathological anatomy was also typically that of an infection, as was also the case with the complications. Dr. Brooks said that it might be due to his lack of skill that he had not met with the marked success in the use of the salicylates which had been Dr. Winters' good fortune. Although the relief afforded by the drug was obvious, he was entirely unable to feel that its employment shortened the course or prevented complications; until he could feel as Dr. Winters that this was the case he could not look upon salicylic acid as a specific in rheumatism nor could he accept his theory as to its action.

Dr. Charles Gilmore Kerley believed that there was unquestionably a chemical factor in rheumatism, and that this represented a means of furnishing a soil that was favorable to the development of infection, the actual factor in rheumatism. Children who partook largely of cane sugar and high fat were in his observation particularly susceptible. He had had the opportunity of seeing a number of cases of autopsies on children who had died with acute articular rheumatism with cardiac complications, and the whole history of the disease, as well as the autopsy findings, bore out the infection theory. The so-called growing pains in children were frequently relieved by the removal of the probable source of the infection, the tonsils. One of the reasons probably that children had rheumatism more than adults, and that they were more apt to develop endocarditis and pericarditis, was because they had a lower resisting power against pathogenic infections. Salicylic acid was useful in some cases; the alkaline treatment was of value in preventing recurrences of the attacks. When a child once had rheumatism in its acute form, with endocarditis, pericarditis, chorea, etc., he was quite sure to have another attack. Placing such an infant on salicylic acid and the alkalies, giving the interval treatment, would often prevent recurrent attacks.

Dr. Walter Lester Carr believed that if they accepted the chemical, uric acid, theory that was for so long the definite view of many able clinicians, they could not fail to agree with most of the papers presented, and their discussion was limited to expressions of acceptance of many of the views advanced. Lithemia undoubtedly lessened the resisting power of cells. If, however, they believed that the word "rheumatism" had a different significance than was attached to it three or four decades ago, and they attempted to explain this wider vision, they became cognizant of the many variations presented by this disease and the extreme difficulty of drawing a clear picture of all the cases that were formerly classed under rheumatism. Up to the present enough had been learned of the etiology of rheumatism to show that the disease was occasioned by microorganisms; the exact organism that produced the majority of cases was not agreed upon by investigators, although the consensus of opinion favored the organism of Poynton and Payne. In almost all the cases the site of infection was the throat, but it was possible to have entrance through the intestinal wall by a process of sub-infection. The diplococcus found in rheumatism had an affinity for mononuclear leucocytes and for endothelial cells. This organism produced formic acid and had a hemolytic action. The formic acid was found in the urine and explained in part at least its acidity during a rheumatic seizure. The hemolytic action of the organism was shown by the anemia present in all these cases.

Dr. A. D. Hirschfelder of Baltimore said that the problems of physical chemistry were so far removed from the ordinary affairs of clinical medicine that clinicians should always be thankful when any one called their attention to them. The pioneer work of Prof. Jacques Loeb, Hans Horst Meyer, and the two Hendersons had shown them the great practical application of such problems to questions of practical medicine. Fascinating as these speculations might be, however, they should not overlook the more obvious revelations of morphology and bacteriology, and he said he could only agree with the previous speakers in accepting the multiple bacterial origin of rheumatic fever. As regards the question of feeding, one important point in the management of heart cases seemed to be that the diet at each stage of the disease should be sufficient to supply the amount of energy (number of calories) used up by the patient, and should be varied to meet the needs, though it should not be made excessive. Schieffer had shown that underfeeding alone might give rise to atrophic changes in the heart, and the experiments of Leo Loeb and Fleisher demonstrated that the interaction of two deleterious agents produced much greater effects than could be attained by one of them acting alone. It was, therefore, most important not to add the injurious effect of malnutrition upon the heart to that of the toxic agent of rheumatism.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

Board of Medical Examiners of the State of California.

San Francisco, August, 1911.

ANATOMY.

Answer Ten (10) Questions Only.

1. Describe the topographical anatomy of the knee, mentioning its bony landmarks and tendons.
2. What is the nerve supply of the flexor group of muscles of the forearms?
3. What are the surface points for the following: Bifurcation of the trachea; gall-bladder; spleen; termination of the spinal cord; kidney?
4. Mention from without inward the tunics of the eye, and describe one of them.
5. Give location of (*a*) deep cardiac plexus, (*b*) celiac plexus, (*c*) aortic plexus, (*d*) Auerbach's plexus, (*e*) Meissner's plexus.
6. Describe the course of the portal vein, (*b*) give its relations.
7. What is the result of total paralysis of the abducent nerve?
8. Describe the venous and arterial anastomoses about the ovary.
9. Name the structures passing through the superior opening of the thorax.
10. What is the origin of the spermatic arteries?
11. What are the surface markings of the liver?
12. Describe the pleural sac, including attachments and contents.

HISTOLOGY.

Answer Only Eight Questions and Identify Four Slides.

1. Describe and locate the characteristic features, which would enable you to tell a section from the skin of the forearm of an Ethiopian from a section of the skin of a Scandinavian.
2. Name the primary blastodermic layers and name (*a*) the structures developed from the mesothelium; (*b*) the structures developed from the mesenchyme; (*c*) the structures developed from the mesameboid group of cells.
3. Describe a section of the human cornea made perpendicularly to the surface. Make drawing.
4. Describe those microscopic features which would enable you to distinguish a section of the thymus gland from a like section of a small lymph gland.
5. What structural differences are there between the Malpighian corpuscles of the spleen and those of the kidneys? Make drawings.
6. Describe the differences to be observed between a transverse section of the trachea as compared with a like section from the esophagus.
7. Describe and make a drawing of a cell that is typical

of: (*a*) the cerebellum, (*b*) the cerebrum, (*c*) the retina, (*d*) the testes, (*e*) the blood.

8. What features would enable you to distinguish a section of the pancreas from a section of the parotid gland.

9. How do the fibers of the peripheral cerebrospinal nerves differ from the nerve fibers found in the brain and spinal cord? Make drawings of transverse sections.

10. What is an erythrocyte? Describe minutely and tell how a normal cell differs in the adult human being from that found in early fetal life.

11. Identify two slides.

12. Identify two slides.

PHYSIOLOGY.

Answer Ten (10) Questions Only.

1. Give proof that skeletal muscle possesses the properties of independent contractility and independent irritability.

2. Define the following physiological terms concerning the phenomena of muscle: Contracture, tetanus, summation, muscle tonus, rigor.

3. Discuss the inhibitory influence of the brain upon the spinal cord.

4. What are the causes of intravascular clotting?

5. How is the blood regenerated after hemorrhage?

6. Describe the coronary circulation during the heart beat.

7. What physiological properties does heart muscle exhibit which differ from those of skeletal muscle?

8. Define the terms intrathoracic pressure and intrapulmonic pressure.

9. What are the general properties of enzymes?

10. What is the origin of the hydrochloric acid in gastric secretion?

11. Describe the absorption of fats.

12. What are the internal secretions of the liver?

CHEMISTRY AND TOXICOLOGY.

Answer Ten (10) Questions Only.

1. Define: Inorganic chemistry; organic chemistry; synthetic chemistry; physiological chemistry; pathological chemistry; pharmaceutical chemistry.

2. Discuss the calcium and chorine groups.

3. How can you distinguish tin from other metals?

4. Give the names and formulæ of compounds of iron used in medicine.

5. How would you make oxygen to be administered to a patient in an emergency when a supply was not obtainable?

6. What does the normal mixed saliva contain?

7. How would you determine the specific gravity of blood?

8. What do the quantitative tests of gastric juice reveal?

9. How do acid albumins and alkali albumins differ; how are they affected by boiling; by acids?

10. What is the chemical treatment of alimentary corrosion caused by mineral acids? Why should the stomach pump be used carefully, if at all, in such cases?

11. Give the chemical and physiological treatment of phosphorus poisoning.

12. Given a urine that reduces Fehling's solution, what poisons would you suspect?

BACTERIOLOGY.

Answer Ten (10) Questions Only.

1. Name the germs which usually cause diarrhea. How would you distinguish Asiatic cholera from summer diarrhea?

2. What causes favus, ringworm, elephantiasis, soft chancre, fermentation of sugar? Give technical names

3. Discuss, not over one page, "*Bacillus diphtheriæ.*"

4. How is yellow fever transmitted? Give in detail.

5. How is tuberculin R supposed to influence tuberculosis?

6. What is the specific test for syphilis? Upon what principle does the test depend?

7. Describe Pasteur's method of neutralizing the poison introduced into a person by the bite of a rabid dog.

8. Describe briefly hemolysis, bactericide, phagocytosis, antitoxin, antigen.

9. Name the germs which are the cause of conjunctivitis. Give 5.

10. How do germs produce pus?

11. Explain briefly natural immunity.

12. Describe Boas-Oeppler bacillus. What is its significance?

GENERAL DIAGNOSIS.

Answer Ten (10) Questions Only.

1. Describe the technique of a lumbar puncture and of what diagnostic value is it.

2. Describe the symptoms and course of meningeal tuberculosa.

3. Give the differential diagnosis in angina pectoris.

4. Describe arthritis deformans. For what may it be mistaken?

5. Describe the following pulses—positives, venous, Corrigan, mollis, dicrotic, bigeminus.

6. Give the etiology and symptoms of iritis.

7. Describe primary pernicious anemia.

8. How would you proceed in examining a chest for incipient pulmonary tuberculosis, and what would you expect to find at each step of the examination in a positive case?

9. Detail the signs and symptoms of a case of aneurysm of the transverse portion of the arch of the aorta.

10. Describe the test breakfast. Describe the methods pursued in determining the presence of (*a*) free hydrochloric acid, (*b*) lactic acid, (*c*) Boas-Oeppler bacillus. N. B.—Quantitative statements as to composition of reagents need not be given.

11. Define (*a*) hallucination, (*b*) delusion, (*c*) illusion, and describe paranoia.

12. What are the complications to be feared in the third week of typhoid fever and briefly enumerate their symptoms.

PATHOLOGY.

Answer Eight (8) Questions and Identify Four Slides.

1. Describe the blood changes in leukemia and what organic changes are usually found?

2. How does scar tissue differ from normal tissues and under what circumstances is it formed instead of normal structures?

3. In the study of tumors or growths what macroscopic and microscopic characteristics would lead you to decide in favor of malignancy?

4. What are usually the immediate causes of death in typhoid fever in the third week, and describe the pathological condition you would expect to find post mortem in such a case?

5. In a severe or neglected case of diphtheria what organic lesions are usually found?

6. Describe fully the permanent changes likely to result from a neglected, long-standing case of gonorrheal infection.

7. What changes take place in the brain in senile dementia?

8. Describe the changes which take place in the eye in glaucoma.

9. Describe the condition of the lungs you would expect to find in a case of death of a child of two years old from pneumonia resulting from a severe neglected attack of measles.

10. Give the pathology of Addison's disease.

GYNECOLOGY.

Answer Ten (10) Questions Only.

1. How would you determine whether cancer of the cervix is operable or not?

2. Amenorrhea, classification, causes?

3. A fibroid tumor, the size of an orange, complicating pregnancy, what would you advise?

4. How would you determine if the pelvic floor is normal in a multipara?

5. Differential diagnosis, appendicitis and adnexal inflammation of the right side.

6. The use of the pessary in retroversion of the uterus, and the mechanism of its support?

7. Diagnosis between the menopause and pregnancy within the first four months?

8. What may be revealed by digital examination of the vagina?

9. Differential diagnosis, ovarian cyst with twisted pedicle and extrauterine pregnancy?

10. Describe a normal menstruation and state the changes that take place in the uterine mucous membrane.

11. What are the common causes of prolapsus uteri? In an operation for its cure, what conditions must be met, and how?

12. Describe the Fallopian tubes and ovaries, what are the natural supports?

OBSTETRICS.

Answer Ten (10) Questions Only.

1. What changes occur in the blood during pregnancy?

2. Give the names and measurements of the diameter of the pelvic inlet?

3. Describe fully the proper management when the head is above the superior straight and will not engage?

4. What do you understand by episotomy, and when is it called for?

5. What methods would you pursue for resuscitation of still-born child?

6. How would you determine that a dead infant had been born alive?

7. Describe conception and what is its physiology?

8. Give (*a*) some of the important intrauterine causes of asphyxia in the new born; (*b*) the external causes?

9. Describe in detail the changes that occur in uterus following childbirth and how long a time is required for involution?

10. In breach presentations describe the different methods of delivering the after-coming head?

11. What do you understand by version? Describe the management in two different forms.

12. What are the more common causes of adherent placenta?

HYGIENE.

Answer Ten (10) Questions Only.

1. Name four points to be observed in personal hygiene to prevent acquiring or imparting tuberculosis.

2. What course would you advise to be pursued to prevent tuberculosis in a child of tuberculous parents? Name four principal points.

3. What are the causes of mouth breathing and what are the deleterious results?

4. Name some special precautions a child should observe at school in order to avoid contracting disease.

5. Describe some practical steps to be pursued by a municipality for the prevention of the spread of venereal diseases.

6. What should be done in prisons to prevent the spread of tuberculosis?

7. In a residence that is heated by a hot-air furnace located in the basement, what should be done to insure that the hot air is pure?

8. What are the hygienic advantages of automobiles over horses at the home and in the city?

9. Why is candy now one of the factors in the diet of American soldiers in the Philippines? What are the usual adulterations to be found in candy?

10. What are the dangers from the house fly? How would you prevent the breeding of flies? Describe three of the best methods of killing flies.

11. Give observations and methods necessary in the inspection of milk.

12. What sanitary precautions should be observed in typhoid fever? Give methods in detail.

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

BOARD OF MEDICAL EXAMINERS OF THE STATE OF CALIFORNIA.

San Francisco, August, 1911.

ANATOMY.

1. See Cunningham's "Anatomy" (1909), page 1307; or Gray's "Anatomy" (1910), pages 331, 337, and 338.

2. The median and ulnar nerves.

3. The *bifurcation of the trachea* is at the level of the spinous process of the fourth dorsal vertebra.

The *fundus of the gall-bladder* is close to the outer margin of the right rectus abdominalis muscle, on a level with the ninth costal cartilage.

The *spinal cord terminates* at the lower border of the body of the first lumbar vertebra.

For *spleen* and *kidney* see Cunningham's "Anatomy" (1909), pages 1210 and 1130; or Gray's "Anatomy" (1910), pages 1448 and 1356.

4. (1) Sclera and cornea; (2) choroid, ciliary body, and iris; (3) retina. See Cunningham's "Anatomy" (1909), page 725; or Gray's "Anatomy" (1910), page 1091.

5. (*a*) The *deep cardiac plexus* is situated in front of the trachea, at its bifurcation, above the point of division of the pulmonary artery, and behind the arch of the aorta.

(*b*) The *celiac plexus* surrounds the celiac axis and root of superior mesenteric artery.

(*c*) The *aortic plexus* is on the sides and front of the aorta, between the origin of the superior and inferior mesenteric arteries.

(*d*) *Auerbach's plexus* lies between the circular and longitudinal muscular fibers of the intestines.

(*e*) *Meissner's plexus* lies in the submucous coat of the intestines.

6. See Cunningham's "Anatomy" (1909), page 902; or Gray's "Anatomy" (1910), page 754.

7. Paralysis of the abducens nerve causes internal or convergent strabismus.

8. See Cunningham's "Anatomy" (1909), page 1185; or Gray's "Anatomy" (1910), page 1403.

9. *Structures passing through superior opening of the thorax:* Sternohyoid, sternothyroid, inferior thyroid veins, trachea, esophagus, longus colli, recurrent laryngeal nerves, apex of lung, internal mammary artery, phrenic and vagus nerves; innominate vein and artery, cardiac nerves, right lymphatic duct, left common carotid and subclavian arteries, thoracic duct, sympathetic and first thoracic nerves, superior intercostal artery.

10. The spermatic arteries arise from the front of the abdominal aorta, a little below the origin of the renal arteries.

11. See Cunningham's "Anatomy" (1909), pages 1286 and 1109; or Gray's "Anatomy" (1910), page 1336.

12. See Cunningham's "Anatomy" (1909), page 977; or Gray's "Anatomy" (1910), page 1183.

HISTOLOGY.

1. See Cunningham's "Anatomy" (1909), page 773; or Gray's "Anatomy" (1910), page 1157.

2. The primary blastodermic layers are the ectoderm, entoderm, and mesoderm. From the *mesothelium* are derived the various endothelial cells which line the serous cavities. From the *mesenchyme* are derived the different forms of connective tissue, as bone, cartilage, fibrous tissue, etc., blood, blood-vessels, lymphatics, spleen.

3. See Cunningham's "Anatomy" (1909), page 726; or Gray's "Anatomy" (1910), page 1093.

4. See Cunningham's "Anatomy" (1909), pages 1220 and 906; or Gray's "Anatomy" (1910), pages 1443 and 771.

5. See Cunningham's "Anatomy" (1909), pages 1213 and 1139; or Gray's "Anatomy" (1910), pages 1447 and 1352.

6. See Cunningham's "Anatomy" (1909), pages 975 and 1041; or Gray's "Anatomy" (1910), pages 1179 and 1238.

7. See Cunningham's "Anatomy" (1909), pages 512, 585, 732, and 1161; or Gray's "Anatomy" (1910), pages 953, 893, 1103, and 1384; and see QUESTION 10.

8. See Cunningham's "Anatomy" (1909), page 1128; or Gray's "Anatomy" (1910), pages 1341 and 1228.

9. See Cunningham's "Anatomy" (1909), page 444.

10. An *erythrocyte* is a red blood corpuscle. It is a circular, biconcave, non-nucleated disc; it is soft and elastic; it contains hemoglobin and a stroma. In the adult it is non-nucleated; in early fetal life it is nucleated.

PHYSIOLOGY.

1. If an animal is curarized and a skeletal muscle is stimulated it will contract, thereby proving it has an independent irritability.

2. *Contracture* is change in the form of a muscle, due to a stimulus.

Tetanus: When stimuli are added so rapidly that the effects of the preceding ones have not had time to pass off the muscle is at no time perfectly relaxed; this condition is called *tetonus.*

Summation: If a muscle which has been stimulated is again stimulated before the effect of the first stimulation has ceased, a second curve is produced which is higher than the first, and is due to the addition of the second stimulus to the former one; this is called *summation of stimulation.*

Muscle tonus is the state of continuous contraction which is generally but slight.

Rigor is the condition into which muscle passes when it dies, or passes from a fluid to a solid state; the muscle shortens, becomes rigid, and does not respond to stimuli.

3. "In the reflex from tickling, for instance, we know that by a voluntary act we can repress the muscular movements up to a certain point; so also the limited control of the action of the respiratory and micturition centers is a phenomenon of the same character. To explain such acts we may assume the existence of a definite set of inhibitory fibers, arising in parts of the brain and distributed to the spinal cord, whose function is that of controlling the activities of the spinal centers. In view of the fact, however, that there is no independent proof of the existence of a separate set of inhibitory fibers within the central nervous system; that is, a set of fibers whose specific energy is that of inhibition, it is preferable to speak simply of the inhibitory influence of the brain upon the cord, leaving undecided the question as to whether this influence is exerted through a special set of fibers or is

brought about by some variation in the time relations, intensity, or quality of the nerve impulses."—(Howell.)

4. *Causes of intravascular clotting:* Damage to, absence of, or disease of the intima or vessel walls: the presence in the circulation of substances not covered by endothelium; retardation of the blood-stream; certain conditions of the blood such as are found after inflammations, diseases, hemorrhages.

5. *Regeneration of blood after a hemorrhage:* "If the bleeding does not go on to death the blood is restored by absorption from the tissues or from the food taken in; the first to be absorbed being the serum sanguinis, with the dissolved salts, and then the albumen. A longer time is required to form new red blood-corpuscles. Regenerated blood is at first abnormally watery and poor in cells. As a result of the greater flow of lymph into the blood the number of white blood-corpuscles is greatly increased, and then their number falls off; the red blood-corpuscles again attain their usual number, and the composition of the blood gradually returns to the normal. We do not as yet know certainly how the restoration of the red blood-corpuscles takes place. The most generally accepted view is that colorless corpuscles are being constantly formed in the lymph glands, in the spleen, in the bone marrow, and in the liver, and a certain number of these colorless corpuscles change into the red disks."—(Tillmann's *Surgery.*)

6. *Coronary circulation during the heart beat:* "During systole, the mouths of the coronary arteries are in free communication with the aorta. But the coronary system—arteries, capillaries, and veins—is in part imbedded in the musculature of the ventricles, and we should suppose that the greater pressure exerted by the contracting musculature would at the height of systole clamp off this system and stop the coronary circulation. That this result really happens is indicated by Rebatel's curves which show a great acceleration in the velocity at the beginning of systole, quickly followed by a drop to zero or even a negative value—indicating a flow in the other direction, toward the aorta. At the end of the first (relaxation) phase of diastole, there is again a sudden increase in velocity, corresponding with the injection of the arteries from the aorta, and this again by a decrease at the end of the diastole at the time when the ventricular cavity is filled with venous blood under some pressure. . . . . The rhythmical squeeze of its own vessels during systole accelerates effectively the coronary circulation."—(From Howell's *Physiology.*)

7. Heart muscle contracts more slowly than skeletal muscle, and also has the power of rhythmic contractility; heart muscle is involuntary (physiologically), whereas skeletal muscle is voluntary.

8. *Intrathoracic pressure* is the pressure in the thoracic cavity outside the lungs.

Intrapulmonic pressure is the pressure in the interior of the lungs and air passages.

9. *General properties of enzymes:* They are generally soluble in water, or salt solutions, or in glycerine; they do not work in extreme temperatures, but require an "optimum" temperature approximating that of the body; they are precipitated by excess of alcohol; they require a suitable medium to work in; the products of their activity must be removed; they are capable of causing change in a large amount of material, while they themselves remain unaltered.

10. *The hydrochloric acid* is formed from the chlorides of the blood in the secreting cells of the stomach. The sodium chloride is broken up and the chlorine combines with hydrogen and is then secreted as hydrochloric acid.

11. *Absorption of fats:* Fats exist finally in the small intestine as glycerine salts and soaps. The columnar epithelial cells certainly absorb these substances, and cause them to combine back, as it were, and thus there appear fine droplets of fat in the epithelial cells. These droplets are then extruded into the subjacent corium of adenoid tissue, where they are taken up by ameboid cells. These cells then pass into the lacteals; some give out their fatty droplets without undergoing disintegration; the majority of them, however, undergo disintegration. There is thus formed in the lacteals an emulsion, with lymph as the suspending agent. This emulsion passes along the lacteals, which converge upon a large lymphatic sac—the receptaculum chyli—whence passes the thoracic duct, to terminate by entering into the angle of junction between the left internal jugular and subclavian. Mixing with the blood, the fat droplets are carried all over the body, and are finally deposited in fatty cells in adipose tissue, probably being carried there from the blood by leucocytes.—(Lack.)

12. *The internal secretions of the liver* are glycogen and urea.

CHEMISTRY AND TOXICOLOGY.

1. *Inorganic chemistry* is the chemistry of compounds which do not contain carbon.

Organic chemistry is the chemistry of the carbon compounds.

Synthetic chemistry is that branch of chemistry which is concerned with the building up of compounds out of elements or simpler compounds.

Physiological chemistry is the chemistry of the living organism and its various processes.

Pharmaceutical chemistry is chemistry in its application to the analysis or synthesis, or preparation of drugs.

2. *The calcium group* consists of calcium, barium, and strontium. These elements are called the metals of the alkaline earths, they are bivalent in all their compounds, they form two oxides, their sulphates and carbonates are insoluble or very slightly soluble, their hydroxides are known as the alkaline earths and have basic characters.

The *chlorine group* consists of chlorine, fluorine, bromine, and iodine. They are called halogens; they are generally univalent; they form hydracids, consisting of one volume of the element in the gaseous form with one volume of hydrogen; they form monobasic acids; they all possess bleaching and disinfecting powers, and are strongly irritant. Fluorine is a gas but can be liquefied with difficulty; chlorine is an easily liquefied gas; bromine a liquid, and iodine a solid.

3. Tin can be distinguished from other metals by the peculiar crackling sound it emits on being bent.

4. Ferrous sulphate, $FeSO_4$; ferrous carbonate, $FeCO_3$; ferrous iodide, FeI_2; ferric chloride, Fe_2Cl_6; ferric sulphate, $Fe_2(SO_4)_3$; ferric hydroxide, $Fe_2(OH)_6$; ferric ammonium sulphate $FeNH_4(SO_4)_2$; ferric hypophosphite, $Fe(H_2PO_2)_3$; ferric citrate, $FeC_6H_5O_7$; ferrous lactate, $Fe(C_3H_5O_3)_2$.

5. Oxygen can be prepared by heating potassium chlorate in a glass flask fitted with a perforated cork and a bent tube for conveying the gas to a pneumatic trough, where it can be collected over water.

$$2KClO_3 = 2KCl + 3O_2.$$

6. *Normal mixed saliva contains:* Water, mucin, albumin, ptyalin, maltase, urea, potassium thiocyanate, potassium oxide, sodium oxide, calcium oxide, ferric oxide, magnesium oxide, sodium chloride, potassium chloride, sodium bicarbonate.

7. *To determine the specific gravity of blood*: Make a mixture of chloroform and benzol, in such proportions that the specific gravity of the mixture is almost 1050 to 1055. Let a drop of blood fall into it. If the blood sinks add more benzol; if it floats on the surface add more chloroform until the blood drop remains suspended. The specific gravity of the mixture is then determined, and is equal to the specific gravity of the blood.

8. Quantitative tests of gastric juice reveal: The quantity of hydrochloric acid, the total acidity, combined acidity, free acidity, and acidity due to organic acids and acid salt, the existence of hyperchlorhydria, hypochlorhydria or anachlorhydria.

9. *Acid albumins* are insoluble in water, in dilute saline solutions and in alcohol. When freshly precipitated they are readily soluble in dilute acids or alkalis, but insoluble when mixed with calcium carbonate suspended in water.

Alkali albumins dissolve very sparingly in water and in saline solutions, slightly soluble in hot alcohol. Shaken with water and calcium carbonate they dissolve, liberating carbon dioxide. They are not coagulated by heat, but are readily precipitated in an acid, if saturated with solution of sodium chloride.

10. Give magnesia suspended in water, or a solution of soap. The stomach pump should not be used, as its introduction may cause perforation of the already corroded tissues.

11. There is no chemical antidote to phosphorus; the physiological antidote is old French oil of turpentine.

12. In a urine that reduces Fehling's solution the following poisons might be suspected: Acetanilide, chloral, chloroform, morphine, antipyrine, copaiba, rhubarb and salicylic acid.

BACTERIOLOGY.

1. See French's "Practice of Medicine" (1910), pages 798 and 292; or Osler's "Practice of Medicine" (1909), pages 505 and 230.

2. *Favus* is caused by Achorion schonleinü: *Ringworm*, by Tricophyton fungus; *Elephantiasis*, by Filaria sanguinea hominnis; *Soft Chancre*, by bacillus of Ducrey: *Fermentation of Sugar*, by Enzymes.

3. See French's "Practice of Medicine" (1910), page 181; or Osler's "Practice of Medicine" (1909), page 194.

4. See French's "Practice of Medicine" (1910), page 267; or Osler's "Practice of Medicine" (1909), page 234.

5. Koch claimed that tuberculin would not directly kill the bacilli, but that it would act powerfully and specifically upon living tuberculous tissue, causing a necrotic condition and hastening its disintegration. He also claimed that it might be expected to increase the resistant power of healthy tissue, and to starve the bacilli, check their increase and so lead to the cure of the disease. (Potter.)

6. The specific test for syphilis is the Wassermann reaction. "The principle involved is that hemolysis does not occur in the presence of a hemolytic amboceptor when emulsions of bacteria are mixed with an inactivated serum with the addition of a complement. The reason is that the complement binds itself with the bacteria and thus prevents the union of complement with the red cell through the medium of the amboceptor." (Wilcox's *Treatment of Disease.*)

7. See French's "Practice of Medicine" (1910), page 461; or Osler's "Practice of Medicine" (1909), page 257.

8. *Hemolysis* is the destruction of the red blood corpuscles by a specific antiserum.

Bactericide is any agent capable of destroying bacteria.

Phagocytosis is the process by which cells (chiefly leucocytes) ingest bacteria or other cells.

Antitoxin is a substance in the serum which neutralizes a toxin.

Antigen is a substance which, when introduced into the animal organism, produces an antibody.

9. *Five germs which may cause conjunctivitis:* Koch-Weeks bacillus, pneumococcus, gonococcus, streptococcus pyogenes, and staphylococcus pyogenes aureus.

10. See Rose and Carless' "Surgery" (1908), page 63; or Da Costa's "Surgery" (1908), pages 42 and 127.

11. See French's "Practice of Medicine" (1910), page 60.

12. See French's "Practice of Medicine" (1910), page 770; or Osler's "Practice of Medicine" (1909), page 483.

GENERAL DIAGNOSIS.

1. See Rose and Carless' "Surgery" (1908), page 759; or Da Costa's "Surgery" (1908), page 763.

2. See French's "Practice of Medicine" (1910), page 348; or Osler's "Practice of Medicine" (1909), page 302.

3. See French's "Practice of Medicine" (1910), page 636; or Osler's "Practice of Medicine" (1909), page 841.

4. See French's "Practice of Medicine" (1910), pages 943 and 948; or Osler's "Practice of Medicine" (1909), pages 389 and 393.

Venous pulse is a pulsation occasionally observed in the jugular veins, owing to some of the blood of the right ventricle flowing back into the right auricle and communicating an impulse to the venous blood entering the auricle from the superior vena cava.

Carrigan pulse is a pulse characterized by a short, sharp, strong impulse, which seems to collapse under the examiner's fingers. It is found in aortic regurgitation.

Pulsus mollis, or soft pulse, is one of low tension and easily compressible.

Dicrotic pulse is one in which the first impulse is quickly followed by another impulse or secondary wave.

Pulsus bigeminus is one in which there are two regular beats followed by a longer pause.

6. IRITIS. *Causes:* Syphilis, rheumatism, gonorrhea, gout, diabetes, leprosy, scrofula, tuberculosis, injury transmission from the eye. *Symptams:* Pain, photophobia, small pupil, ciliary congestion, discoloration of iris, exudate in anterior chamber.

7. See French's "Practice of Medicine" (1910), page 516; or Osler's "Practice of Medicine" (1909), page 724.

8. See French's "Practice of Medicine" (1910), pages 346, 362 and 375; or Osler's "Practice of Medicine" (1909), page 301.

9. See French's "Practice of Medicine" (1910), page 646; or Osler's "Practice of Medicine" (1909), page 855.

10. See French's "Practice of Medicine" (1910), pages 1222 and 1224.

11. A *delusion* is a belief in something which has no real existence, but is purely imaginary; and out of which the person cannot be reasoned. An *illusion* is a false or perverted impression, received through one of the senses. An *hallucination* is the same as an illusion, but without any material basis.

If an individual believes himself to be made of glass, and is afraid of being touched lest he be broken, he is suffering from a *delusion*. If the whistling of the wind is mistaken for a voice telling a person to do a certain thing—that would be an *illusion*. If a person fancied he heard a voice when there was nothing at all to be heard, that would be an *hallucination*.

Paranoia is a primary chronic form of insanity, occurring especially in degenerates, and marked by hallucinations and delusions which are systematized, *i.e.* exhibit a logical connection and sequence, so that the patient from his perverted ideas, in which he firmly believes, draws logical and coherent influences. (From Duane's *Medical Dictionary.*)

12. See French's "Practice of Medicine" (1910), pages 81 and 86, etc.; or Osler's "Practice of Medicine" (1909), pages 70 and 80, etc.

PATHOLOGY.

1. See French's "Practice of Medicine" (1910), pages 526, 529, and 530; or Osler's "Practice of Medicine" (1909), page 732.

2. See Rose and Carless' "Surgery" (1908), page 255; or Da Costa's "Surgery" (1908), page 114.

3. See Rose and Carless' "Surgery" (1908), page 186; or Da Costa's "Surgery" (1908), page 301.

4. See French's "Practice of Medicine" (1910), pages 70, 77, and 86; or Osler's "Practice of Medicine" (1909), pages 66 and 80.

5. See French's "Practice of Medicine" (1910), page 190; or Osler's "Practice of Medicine" (1909), pages 199 and 203.

6. See French's "Practice of Medicine" (1910), page 217; or Osler's "Practice of Medicine" (1909), page 282.

7. "The characteristic change of *senile dementia* consists of a general sclerosis of the arteries of the brain, often with hyalin fibrous degeneration. Sometimes the great vessels are intact while the small vessels and capillaries are diseased. There is an attenuation of the bones of the cranium, the diploe is visible (malum senile), generally external and internal pachymeningitis are present, quite often with hematomata, clouding of the arachnoid inlaid with calcareous plaques, large Pacchionian granulations, atrophy of the brain cortex, especially of the frontal lobes, and granulations of the ependyma. In a third of all cases there is hemorrhagic or thrombotic softening of the brain: further, sclerotic changes in the spinal cord. Microscopically, the atrophic brain shows hypertrophy of the neuroglia, sometimes with miliary sclerosis of the cerebral cortex, disappearance of the tangential fibers, decrease of the number of the nerve cells of which those present are atropho-pigmentous, and fatty degeneration with chromatolysis. The smallest vessels and capillaries often seem destroyed, sometimes changed into strings without lumen. The peripheral nerves often show signs of a degenerative neuritis."—(Mendel-Krauss.)

8. In *acute glaucoma:* "Objective examination reveals marked increase in tension; the cornea is clouded or steamy (due to edema), often presents punctate opacities, and is insensitive (from pressure upon nerve filaments): there is pronounced circumcorneal injection of a dark red color; the episcleral veins are prominent. The pupil is dilated, oval, immobile, and often presents a greenish reflex. The iris is congested, discolored, and dull. The anterior chamber is shallow, the aqueous sometimes turbid. The lens and the periphery of the iris are pushed forward. The lids are swollen and edematous. The ocular conjunctiva is markedly congested and chemotic. No details of the fundus can be seen with the ophthalmoscope, on account of the clouding of the media."—(May.)

9. See French's "Practice of Medicine" (1910), pages 329 and 687; or Osler's "Practice of Medicine" (1909), pages 143 and 622.

10. See French's "Practice of Medicine" (1910), page 549; or Osler's "Practice of Medicine" (1909), page 756.

GYNECOLOGY.

1. Cancer of the cervix is only operable when the disease does not extend beyond the uterus; and if the vagina, or broad ligament, or rectum, or bladder, or pelvic cellular tissues are involved, an operation is useless.

2. Amenorrhea is the absence of menstruation.

It is *physialogical:* Before puberty, during pregnancy and early lactation, and after the menopause. Otherwise, it is *pathological*, and may be due to: Absence or imperfect development of the generative organs; also to stenosis, obstructions, or atresia of the genital tract: also to operative removal of the uterus or its appendages. Other causative factors are: Acute infectious diseases, anemia, chlorosis, obesity, drug habits, alcoholism, overstudy, lack of exercise, exposure to cold and various emotional causes. When due to anemia, chlorosis, etc., it is said to be *canstitutional.* Amenorrhea is also called *primary* when the flow has never been established; *secondary*, when it is suppressed.

3. See Williams' "Obstetrics" (1909), page 674; or Hirst's "Obstetrics" (1909), page 223.

4. See Hirst's "Obstetrics" (1909), page 607.

5.

APPENDICITIS.	TUBO-OVARIAN DISEASE.
1. No previous local disturbances.	1. Genitourinary functions previously disturbed. Usually a history of gonorrheal or puerperal infection
2. Chill usually absent.	2. Chill may precede fever.
3. Pain in right iliac region, sudden onset, acute, and not radiating to thighs.	3. Gradual onset, pain dull, continuous, and radiating.
4. Fever of variable degree.	4. Fever often entirely absent.
5. Musular rigidity on right side of the abdomen.	5. No muscular rigidity unless complicated by peritonitis.
6. Inflammatory exudate about appendix three to five days after onset of symptoms.	6. Inflammatory exudate in the pelvis felt by vaginal examination at the onset of the symptoms.
7. Vaginal examination is rarely painful in appendicitis.	7. Always painful in tubo-ovarian disease.

—(Findley.)

6. The pessary is only indicated in the absence of adhesions and inflammation, and when it can be worn without discomfort. "The vaginal pessary retains the uterus in place by raising the posterior vaginal fornix and keeping tense the posterior vaginal wall. The posterior wall of the vagina runs over the upper transverse bar of the pessary like a rope over a pulley; therefore there is maintained a continuous traction in an upward and backward direction upon the cervix, and a resulting continuous tendency to throw the fundus uteri in a forward position. The tension of the posterior vaginal wall and the traction upon the cervix vary with the position and occupation of the woman, and are increased by anything that increases the intraabdominal pressure. The vaginal pessary does not maintain the uterus in place by pressure upon the body of the uterus, nor does the vaginal pessary correct a retrodisplacement. The uterus should be restored to its normal position as nearly as possible before the pessary is introduced."—(Penrose.)

7. In the *menopause* there is cessation of menstruation; but none of the other signs of pregnancy. See Williams' "Obstetrics" (1909), page 190; or Hirst's "Obstetrics" (1909), page 204.

8. From *a digital examination of the vagina* can be learned the presence or absence of vaginismus; the size, position, temperature, sensitiveness, moisture, and laxity of the vagina; the presence of foreign bodies, hernia, fissures, or caruncles; the position, form and consistency of the cervix uteri; lacerations (including position, number, extent and direction), erosions, growths, or cysts on the cervix; prolapse, displacements and size and position of the uterus.

9. EXTRAUTERINE PREGNANCY.	OVARIAN CYST.
1. Rapid and regular growth.	1. Slower growth.
2. Amenorrhea, followed by menorrhagia, with discharge of pieces of decidua.	2. Menstruation not altered except occasionally in broad-ligament cysts.
3. General symptoms of pregnancy present, changes in color of vagina, etc.	3. Symptoms of pregnancy absent.
4. Enlargement of the uterus.	4. No enlargement of the uterus.
5. Attacks of pain increasing in severity, finally culminating in a very severe attack, followed by shock and symptoms of internal hemorrhage.	5. In small cysts, no attacks of pain except from pressure.
6. Pain is intermittent.	6. The twisted pedicle may cause sudden and acute pain.

(From Wells.)

10. See Williams' "Obstetrics" (1909), page 81; or Hirst's "Obstetrics" (1909), page 58.

11. PROLAPSUS UTERI. *Etiology:* Injury at childbirth, lacerated perineum, relaxation and elongation of the ligaments of the uterus, loss of rigidity of the abdominal walls, increase in the weight of the uterus, subinvolution, increased intraabdominal pressure. *Treatment:* "A prolapsed uterus must first be placed in proper position, or a procidentia reduced. In many cases the introduction of a rubber ring pessary will then suffice to prevent recurrence. But it will often be found necessary to repair a torn perineum, removing at the same time redundant portions of the vaginal walls, before the ring will remain in the vagina. When such an operation is contraindicated, and the vaginal orifice is so wide that a ring cannot be kept in, some form of pessary with a vaginal stem and perineal bands will be required. In cases of procidentia, where the exposed surface is much ulcerated, the patient should be kept in bed, emollient applications made to the ulcers, and vaginal douches given. When the ulcers have healed, a pessary may be introduced. Procidentia due to supravaginal elongation of the cervix must be differently dealt with. Amputation of a portion of the cervix must therefore form the first step in the treatment, and it may be required also when the hyperplasia is secondary to descent. Cases of prolapse and procidentia which resist milder measures require further operative procedures, such as ventrofixation of the uterus or the shortening of the round ligaments. It is in cases of this kind that hysteropexy has often given satisfactory results. Total extirpation of the uterus has been advised and practised for the treatment of procidentia."—(Sutton and Giles' *Diseases of Women.*)

OBSTETRICS.

1. See Williams' "Obstetrics" (1909), page 172; or Hirst's "Obstetrics" (1909), page 185.

2. See Williams' "Obstetrics" (1909), page 4; or Hirst's "Obstetrics" (1909), page 22.

3. Empty the bladder and rectum; determine if there is a faulty presentation, as bregma, brow, or face. Measure diagonal conjugate and height of symphysis and determine the true conjugate. If this latter measures less than 2¾ inches in a simple flat pelvis, or 3 inches in generally contracted pelvis, the contraction is absolute, and only cesarean section or craniotomy is possible. Ascertain by palpation whether there is serious disproportion between head and pelvis. Malpresentations must be corrected with one hand in vagina pressing upward on the fetal anterior portion of the presenting part, and if possible drawing down in the occipital pole, aided by external manipulation. Press the head downward into the pelvis; this maneuver may be aided by Walcher's position. If there is marked disproportion, cesarean section and craniotomy must be considered. If disproportion is apparently not insuperable, rupture the membranes just after the acme of a pain, when the cervix is fully dilated, keeping the patient in Walcher's position. If the head thereupon engages during the next few pains, allow spontaneous delivery, or aid with forceps if necessary. If the head still refuses to engage, apply axis-traction forceps in Walcher's position, tentatively; if unsuccessful, perform podalic version by combined or internal method. If membranes have already ruptured, note whether there is marked retraction ring. If not, podalic version is proper, subject to limitation of slight disproportion; but if the uterus has retracted markedly, forceps, and that failing, only cesarean section, symphyseotomy, or craniotomy is admissible.—(From Scott's *State Board Obstetrics.*)

5. See Williams' "Obstetrics" (1909), page 846; or Hirst's "Obstetrics" (1909), page 939.

6. *Application of Hydrostatic Test.*—Having opened chest, note *position* of lungs (*before* respiration they occupy a small space at upper and posterior parts of thorax); their *volume* (of course increased after breathing); their *shape* (before respiration, borders sharp or pointed; after it, rounded); their *color* (before breathing, brownish-red; after it, pale red or pink), their appearance as regards disease and putrefaction; and whether they *crepitate* on pressure (as they will *after* respiration).

"Take out lungs, with heart attached, and place them in pure water having temperature of surrounding air. Note whether they float (high or low), or sink (slowly or rapidly). Separate them from the heart; weigh them accurately, and then place them in water again, and note sinking or floating as before. Subject each lung to pressure with the hand, and note sinking or floating again. Cut each lung in pieces and test floating again. Take out each piece, wrap it in a cloth, and compress with fingers as hard as possible, and test floating, etc., as before. The crucial test of *perfect respiration* is each piece floating after the most vigorous compression."—(King's *Manual of Obstetrics.*)

HYGIENE.

1. (1) Careful disinfection or burning of sputum; (2) avoidance of spitting in public places; (3) plenty of fresh air and sunlight; (4) avoidance of kissing.

2. (1) The child should not sleep in the same bed with the parent; (2) the child should (if possible) have a sleeping room to itself; (3) avoidance of kissing; (4) the child should be kept in the open air and sunshine as much as possible, and should be well and suitably fed.

3. See French's "Practice of Medicine" (1910), page 736; or Osler's "Practice of Medicine" (1909), page 447.

4. *The principal means of preventing the spread of contagious diseases in schools* are: Regular and efficient inspection by physicians; prompt exclusion and isolation of anyone suffering from a contagious disease, or coming from a house where such disease is; compulsory vaccination; compulsory notification of all infectious and contagious disease; individual towels, drinking vessels, and other implements; children who have had a contagious or infectious disease, or who have come from a house where such disease prevailed, should not be readmitted to school until sufficient time has elapsed since the occurrence of the last case to insure safety.

5. *Practical steps to prevent the spread of venereal diseases in a community*: (1) The scientific and practical control of prostitution (this is always oposed); (2) the education of the public on the dangers of venereal diseases (this is generally opposed); adequate instruction in hygiene in the public schools.

6. The cells should be disinfected after the removal of each prisoner; tuberculous prisoners should have their individual cups and eating utensils and implements; also cloths and towels for their own use; spitting should be prohibited except in receptacles specially provided for the purpose; sputum should be disinfected or burnt.

7. The air should be filtered before it reaches the furnace.

8. *Hygienic advantages of automobiles over horses:* Absence of stables, manure, etc., flies; hence greater cleanliness and comfort, and less disease.

9. Candy is an important factor in the diet of the soldier on account of the sugar it contains. The sugar gives strength to muscles and helps to produce fat; it delays fatigue, and increases working power. After much hard work, sugar quickly revives and restores the jaded muscles.

Usual adulterations in candy: Terra alba, glucose, starch, cocoa butter, coloring agents.

10. The house fly is one of the commonest agents in the transmission of disease. *To prevent the breeding of flies*, keep the house and surroundings clean; cover up garbage, burn sputum, leave no dirt or manure in yard or stable. *To kill flies*: Catch them in traps or on flypapers, and then burn them; or "swat" them.

11. *For milk:* The inspection should include: the color, reaction, specific gravity, sediment, taste, odor, acidity, total quantity of solids and of water; the percentage of cream, fats, lactose, casein and ash; the presence or absence of preservatives, coloring matter, added solids, dilution, pathogenic microorganism, dirt or other foreign matter. There should also be thorough investigation as to its source, the cows and their environment, the method employed in caring for, milking, storing, and transporting the milk.

12. See French's "Practice of Medicine" (1910), page 107; or Osler's "Practice of Medicine" (1909), page 96.

Lemons in Fetid Bronchitis.—Kobert has recommended lemons by inhalation and per os for the fetid breath and sputum of pulmonary gangrene, phthisis and bronchiectasis. The communication was made before the Aesztlicher Verein at Essen-Ruhr by Grober. Kobert finds lemons superior to the old and time-honored turpentine for the purpose indicated. Lemons artificially purified are used, the oil being strongly antiseptic and having a pleasant odor and taste. The substance employed is apparently the commercial product used largely with us for flavoring jelly and making lemonade.—*Berliner klinische Wochenschrift.*

PSYCHANALYSIS AND CORRECTION OF CHARACTER.*

BY E. W. SCRIPTURE, Ph.D., M.D.,

NEW YORK.

ASSOCIATE IN PSYCHIATRY AT COLUMBIA UNIVERSITY.

A PERSON'S character is unknown to himself. When his characteristics are told to him he instinctively adopts an attitude of opposition. Direct correction proceeds against this resistance. When, however, the characteristic appears to him through psychanalysis it has the effect of a personal discovery which impresses itself deeply on his mind.

Methods must be used that reveal just those most fundamental traits of the person's character which are unknown even to himself. One such method is that of objectification. This I learned from Dr. Jung. The patient is instructed to report all impromptu thoughts concerning the doctor that occur to him.

One patient said that he thinks I am inclined to flights of fancy and to be fundamentally theoretical, and that much of my work has no system. I recalled to him the familiar illustration of a group of travelers who were called upon to make observations on a given object. One man remarked on its manufacture, another on its beauty, another on its salability, etc. It was not difficult to tell that one was a manufacturer, another an artist, the third a commercial traveler, etc. Each one revealed the domain of life in which his thoughts were mainly involved. I then said to the patient that every one made remarks about me according to his own special characteristics, and I asked him, "Are you not fundamentally theoretical and superficial? Don't you have trouble in working systematically?" It struck him as a new thought. Yes, his greatest worry was in the details of life; he took general views of business matters without systematically verifying details. I then pointed out to him that this was a fundamental trait of his character which could be read in his expensive but sometimes neglected clothing, in his generous but sometimes offensively careless manner, etc. Gradually it dawned on his mind that this trait was to a large extent the ruin of his best prospects in life.

Another patient for a long time reported only impromptu thoughts such as "You always wear a collar with turned corners," "You part your hair on the right side," etc. I pointed out to him that those thoughts were not about me personally and that he was merely putting me off in order not to express what he really had in mind. Finally he reported that it had occurred to him that the doctor was essentially a timid man. I explained the principle as in the preceding case and he at once told a long tale of his suffering from intense timidity—a suffering almost beyond belief—that was the ruin of his life. After the resistance had once been broken down the thoughts came freely and the cure proceeded successfully.

Another patient reported, as impromptu thoughts, that the doctor's hair was getting thin and that he was beginning to be stout. The motive for these thoughts was his worry about his own advancing age.

Another patient said: "Your tact and consideration for my feelings are greater than in any one I have ever met." I replied, "It is *you* who are so considerate of other person's feelings." This and similar work led to a picture of the person's mind that was appalling. He was always worrying about what each person thought of him, he lived in constant terror at meeting people, a terror that was unknown to any one but himself. He had never clearly recognized that he alone and not everybody lived in such terror.

Dreams are remarkably effective in revealing unsuspected traits of character. After I had been treating a stutterer for a long time with steady and satisfactory progress, I decided to accelerate the cure by remodeling his character. At the very first treatment he related a dream that occurred while away from home. "I am at home on my farm, and visit the stable. Somehow I get to know that my favorite horse is ill." On arriving home he was told that the horse was actually ill. I asked, "Were you worrying about the horse while away?" He replied, "No." I pointed out that the dream expressed either a wish or a fear that was subconsciously present. He then told me what I had never suspected from two years of acquaintance with him, namely, that he was a chronic worrier. He worried about every trifle in life. He had not consciously worried about the horse but this dominant trait had shown itself even in this simple dream.

Let me now briefly explain some of the well-established laws of dreams.

A little girl eight years old had received a present of some Bantam chickens; she was rather disappointed at their smallness and at the fact that they could not be expected to grow larger. The next morning she related in great glee that she had dreamed she possessed a number of big Cochin China chickens. She had owned some Cochin China chickens the preceding summer. The incidents of the dream were furnished by events of the preceding day (owning the Bantams) and of a time not long before (the Cochin Chinas). The incidents of the dream we will call its "manifest content." The study of thousands of dreams has established as a first principle that the manifest content is derived mainly from events of the day before or of a recent time.

Why should the little girl have a dream substitut-

*Address before the American Neurological Association, Baltimore, 1911.

ing large chickens for small ones? Her pleasure the next morning gives us the answer. The Bantams disappointed her; she would have preferred Cochin Chinas, that is, she really wished for them, although she probably did not recognize that she had a wish. This wish had not been fulfilled in reality, the dream fulfilled it. The study of thousands of dreams establishes the fact that they are largely made up of realization of wishes that have not been fulfilled in reality.

The fact of the wish does not appear to the dreamer. He does not dream that he is wishing something but that he has it. The wish is an element deduced from the incidents of the dream. Such elements established by deduction belong to what is called the "latent content" of the dream.

One patient reported to me that she dreamed I told her not to write out her dreams. She confessed that the duty of writing out her dreams was very irksome; the latent wish not to do so was fulfilled in the dream. Another dreamed that he had lost the paper I had given him for the purpose. When I told him that this meant that he really wished he had lost it, he confessed that every night it had irritated him to think that he must get up and record any dream he might have. Neither of the patients suspected that the dream expressed a wish.

In these and many other cases the latent content of the patient's dream expresses a wish; the manifest content shows what the wish is about.

I have found a whole class of dreams that express fears. A brief dream of a patient represented him as quite bald and much worried about the fact. This expressed a very deep-seated fear that he has. If the dream had made his hair grow out again or if it had suggested some remedy, a wish would have been present. The dream, however, confined itself strictly to the picture of a condition that he feared was approaching.

The latent content of dreams consists of the personal impulses of the dreamer. This is the principle that I would substitute for Freud's statement that a dream is an expression of a wish. My facts show that at least two fundamental impulses—wishing and fearing—are present.

Wishes and fears may both be present, sometimes in the same incident. One patient relates a dream of a journey to his sweetheart: "At the end of the journey I get to know (I don't know how) that she is lost to me, having married another man. I awake crying bitterly." The statement expresses as a fact something he evidently fears. The man was so distracted with this love affair that his health and business were almost ruined. I said to him, "Don't you see that the dream expresses the very best thing that could happen to you? You would be much hurt, but wouldn't you be immensely relieved to find that the girl had accepted some one else and that this worry was finally settled? Down in the bottom of your soul don't you really wish she would do it?" This new aspect of the matter seemed to strike him favorably.

Why do the personal impulses have more effect in dreams than in waking life? In waking life our wishes, fears, other emotions and instincts, our ideas of our own importance, in short, all our feelings and ideas concerning ourselves, are subject to overpowering modification and repression by our surroundings. We do not eat just as we like because custom confines us to meal times. If we see an enticing bunch of grapes in a fruit store, we do not help ourselves because we know that we will get into trouble unless we go through the formality of paying for them. We do not kill the man we hate, or steal the woman we love, because we know the penalty to be too severe. But when we are asleep we are not so forcibly reminded of these restrictions, and we can let our thoughts come far more freely. While awake, the little girl knew that she could not have Cochin Chinas, but there was nothing to hinder her from having them in her dream. Awake we may not take the bunch of grapes or kill the man or steal the woman as our own impulses urge us to, but in dreams we can do so freely.

What is the relation of the manifest content to the latent content? The latent content contains the fundamental impulses of the person, the manifest content expresses them directly or in symbols.

A patient related the following dream: "I am on the train. The conductor comes for my ticket. I have lost it. This annoys me. The conductor insists on payment and I have to buy a new ticket; at this I am very angry. On arriving home I am worried for having forgotten in the train the roll of paper that the doctor had given me to write my dreams on."

When asked if anything relating to a ticket on a railway journey had occurred lately, he replied that it had been previously arranged that he should go on a business journey to Chicago at the expense of the firm. The business had just been settled by mail and he had thus "lost his ticket." He had decided, however, to go at his own expense ("pay his fare") in order to see his sweetheart (the unfulfilled wish) whom he always visits when business takes him to Chicago. The sheet of paper beside his bed for recording his dreams is a constant worry to him. The dream realizes the unconscious wish that it would get lost just like the ticket.

There was nothing in the dream that differed much from ordinary life; the symbolism is very transparent. "Lost his ticket" is symbolic for "lost his journey," "paying again" for "going again." Yet the patient had not the slightest idea of the meaning of the dream.

How does this habit of translation into symbols arise? When we allow ourselves to think freely, a multitude of thoughts arise at each instant. Automatically we select those that are most intimately connected with the main topic of thought. This automatic control extends even to the topics concerning which we allow ourselves to think. From earliest infancy we are taught to control our impulses. In early childhood we learn that there are topics which we must not talk about—and some concerning which it is quite improper even to think. Automatically we learn to shut off all thoughts that arise concerning such topics; we simply do not allow ourselves to think about them. The most important of these topics is that of sex. The natural impulses of children to investigate sex matters are shut off abruptly and it thus becomes a mysterious topic concerning which the child must not allow himself to think.

If, however, we can disguise a topic by putting it into symbols, then it can be thought about. A dream will often present at great length in allegorical form some topic which in its bare-faced form would be inacceptable to the dreamer.

The habit of translating being fixed in our minds, most dreams occur in translations although their content would not offend the automatic censorship. I could relate innumerable dreams carried on in symbols where I am sure that the directly expressed

content would have pleased me just as well or better.

A patient relates the following dream: He observes a series of criminals marching along in line, having their right hands raised with a wisp of straw and hay tied to each. They are marching into a church. The priest begins to deliver a sermon at which all of the women are offended and leave the church. The criminals are condemned to be burned for the crime of free speech. They are taken outside and the sentence is executed.

The patient is a stutterer. His attitude toward the persons condemned for free speech suggested that he had a rather natural envy and resentment toward those who did not stutter. He confessed that this was exactly the case. Envy and revenge are nearly related. In the dream he revenges himself on people who can speak freely by representing them as criminals and having them executed by burning. It is a well-established rule that all the principal figures in a dream represent the dreamer. The priest therefore was the person himself, evidently getting great pleasure in condemning these convicts. The other incident of the dream is explained by a fact that I happened to know concerning the patient. He had made up his mind to say a certain thing in case he should ever contemplate being married. I had told him that such an act would drive any woman away from him, and he replied, "I will never get married then." The dream expressed the fear that this thing would happen.

The symbolism of dreams is exactly that of daily life put into pictures. During the day we speak of "washing the dirty linen"; in dreams we actually see it washed. We speak of a person as being a "bad egg"; in a dream we actually see the bad egg and not the person. School and college boys often talk largely in symbols without realizing it; there is usually a kind of vulgar swaggering humorousness about it. Naturally enough the same style appears in the dream symbols. One patient dreams of himself in his automobile as "putting on speed down hill" after I had scolded him for studying recklessly late into the night. Another man might have dreamed of a candle burning at both ends to represent the same thing. One patient's disappointment in a love affair is represented by a wedding at which he gets only a drink of sarsaparilla. The familiar "to be snowed under" appeared in one man's dream which represented him as trying to escape from a fierce snowstorm; it was a symbol for his depressing financial difficulties.

The translation of the dream back into its original elements may occur by having the patient start with any item of the dream and then relate all the thoughts that occur to him spontaneously. This is the method of "running associations." Sooner or later the patient hits upon some thought that he feels is identical with a fact in the dream.

As the method of running association requires considerable time, I prefer one of the following procedures. I tell the patient to write out the dream and to keep going over it during the day, thinking of what events of the preceding day may have brought about the dream and looking for any wishes or fears that may suggest themselves. He will often come back with the translation worked out.

The results that are obtainable when these methods are applied to the correction of character are surprising. One young man reported his dreams and observations to me almost daily for two months. In the dream he was constantly attending receptions, ceremonials, marriages, etc., and meeting celebrated people. This brought out the fact that he was so sensitive that he suffered extremely in meeting any one, even members of his family. His observations about the doctor referred to his gentleness, kindness, sympathy, and tact; these were qualities that he needed but missed in the world, even in his own family. As the nature of his sensitiveness became clear to him, he experienced relief from the very start.

The principles involved in the formation of character may be sketched as follows: There is first the inherited disposition. The infant arrives with a number of wants such as air, food, etc., to satisfy which he performs certain acts. The satisfaction gives him relief or pleasure. This instinctive feeling of want needs a special name—perhaps we can call it "libido." All things and persons that satisfy these wants—this libido—become objects of love. The infant loves his nurse or his bottle, he loves his own thumb which he can suck.

That portion of the libido directed to others we term "hetero-erotism," that portion directed toward himself "auto-erotism."

Normally the child loves mother, father, brother, and self in varying proportions. Often the mother keeps too close to the child, pets him, lives too intimately with him, etc. In some cases this may produce the self-centered child.

One boy that was brought to me was considered to be mentally and morally defective by several people. The condition was a very simple one of complete egotism. His mother had coaxed or wheedled him always and had never forced him to do anything that he did not wish. He was a perfect tyrant over the household. He would strike anyone that displeased him. When a new governess asked him what he was striking her for, he stated, "To make you afraid of me." She replied, "I am not afraid of you." Thereupon he stood in thought for a while and finally got out a toy sword and ran at her with it, exclaiming "Now I have found something that will make you afraid." On the other hand, in the company of other boys he was himself afraid of them. All his thoughts were centered on himself and other persons were to him either objects that feared him or objects to be feared.

Quite frequently the mother-relation produces not auto-erotism but a maternal-erotism in the child. He loves his mother so abnormally that the passion is as strong as a sexual one. Often these boys become unable to love or marry other women.

Sometimes the child is kept too close to the father; this is often the case with girls. This leads to an unrecognized jealousy on the part of the mother. I have now one case in which the girl's entire life is being sacrificed because the mother thinks she is doing the best for her and is yet driven by an unrecognized jealousy to choose a course of life that is to her detriment.

The original libido which was directed toward bodily wants and satisfactions may be turned into other channels. A most frequent case is the sublimation of the libido into ambition, scientific spirit, or the like. The origin of scientific fervor was very evident in the case of one patient, a college professor. As a young man he had lived an absolutely abstinent sexual life, but had been driven by a wild ambition to achieve distinction in science. His laboratory he had fitted up with care for details of decoration and beauty that reminded one of the way a woman would select her clothes. His account of his laboratory sounded like a lover's en-

thusiastic description. It was evident that his abnormally strong sexual instinct had been sublimated into love for his laboratory and for his science.

I believe we can quite agree with Freud that the permanent traits of character are unaltered continuations of the original infantile instincts, or sublimations of them or reactions against them.

Among the methods of therapy for character defects, psychanalysis is certainly one of the most effective. I have had boys and young men living with me in the closest of intimacy for months and years without ever being able to know them as thoroughly as now after a few weeks of psychanalysis. There are two reasons for this: the psychanalysis brings about an intimacy that cannot be attained in any other way and it reveals the traits of character that would otherwise remain unknown to anyone. The analysis itself is a vital part of the cure; as the patient recognizes his abnormalities in this way he instinctively corrects them. It is most effective to combine psychanalysis with educative treatment.

Various objections have been raised to psychanalysis. The most frequent is that there is too much talk about sexual matters. Such discussion is, however, often entirely unnecessary. When it occurs, it can be done with such delicacy as not to offend the most modest person.

Another criticism of psychanalysis is that it takes a great deal of time. This shows an entire misunderstanding of the case. Psychanalysis is valuable for just the reason that in some cases it achieves results in a far shorter time than they can be attained in any other way, and in other cases it is successful where other methods are hopeless. In character treatment the improvement begins immediately and the results are apparent from the start.

130 West Seventieth Street.

WHY IS THE APEX THE POINT OF ELECTION IN TUBERCULOSIS OF THE LUNGS?

By THOS. G. McCONKEY, M.D.,

San Francisco, Cal.

In order to understand better the nature of tuberculosis, it is imperative to seek the point of view of the naturalist rather than that of the physician called to treat the patient. The naturalist sees two species to study, one of which is the parasite of the other, and he knows that "nature" is as much concerned in the continuance of the parasite as a species as she is in the host as a species. The doctor, whose function it is to strive to suppress the parasite, is very prone to regard it simply as an agent whose sole purpose and effort is to kill his patient. The naturalist knows, on the contrary, that the longer the host lives and comes in contact with his own species and disseminates the parasites or their infecting material the better it is for the parasite as a species. In other words, killing the host has no "survival value" for either the host or the parasite. In fact parasitism is only possible when a mode of *living* together has been evolved through the laws of heredity and adaptation.

There are several views as to the mode of entrance of the bacillus into the human body, but unanimity as to its usual mode of exit. Nature depends upon the lungs for the multiplication and the scattering abroad of the bacilli in such prodigal numbers that the continuance of the species is assured. When it was learned that the bacilli are coughed out through the air in "open" tuberculosis it was naturally but none the less erroneously assumed that the progenitors of these bacilli reached the lungs directly through the air and this mode of entrance was confirmed apparently by the presence in the lungs of minute dust particles in those who had inhaled such dust. So obvious did this mode of entrance seem to be that it was and unfortunately still is accepted without question, speaking generally.

When it was found that tuberculosis of the lungs could be caused by the ingestion of tubercle bacilli or by inoculation even as far distant from the lungs as the end of the tail of a calf, the inhalation theory began to be questioned. Hence arose the two opposing views—the old inhalation and the new ingestion view. The "ingestionists" proved that even the dust particles found in the lungs of those inhaling these particles did not reach the lungs directly through the air, as had always been assumed, but through absorption by the lacteals of the digestive tract and thus reached the lungs *via* the thoracic duct and the veins. When it was proved for all time that pneumonoconiosis in its numerous forms, such as anthracosis, or coal-miners' disease, "steel-grinders' phthisis," and all that genus was due to the *swallowing* of the dust particles, which was proved by the simple experiment of tying the esophagi of the animals, causing them to inhale dust and then feeding them. Normal control animals showed dust in the lungs, while those incapable of swallowing the food were free from dust particles in the lungs, the main prop of the "inhalationists" was removed. The value of this discovery does not lie solely or even mainly in proving that tuberculosis of the lungs may result from the ingestion of tubercle bacilli. The discovery of the circulation by Harvey was incidental to the controversy of the venesectionists (and practically all doctors were venesectionists) as to the best *place* to bleed. Harvey showed that inasmuch as the blood traveled in a circuit it did not matter from which point it was taken. When we all realize fully that the tubercle bacilli reach the lungs through the lymphatic *circulation* we shall be in a better position to understand why in tuberculosis of the lungs the apex is first invaded. It matters little at what point the bacillus enters the lymphatic circulation of those predisposed to phthisis, it will eventually get a lodgment on the pleura, and having penetrated it finds itself in an air vesicle under ideal conditions for its multiplication and for this progeny to reach the outside world and thus continue the species. This aërobic bacterium now finds itself not only in air, but in air filtered of more rapidly growing bacteria. It is in that part of the lung most easily spared by its host and which, through gravity, insures its progeny reaching the larger bronchi. We can imagine a drop of the secretion excited by the presence in the air vesicles of the colony of bacilli reaching a larger bronchiole or bronchus perhaps as a hanging drop, which is converted into spray by the forcible current of air caused by the act of coughing, just as an atomizer causes a spray. We thus see why the apex is the best place from the standpoint of both the host and the parasite—the host is least discommoded and the parasite has the best chance of reaching a new host.

That this is a very live question, awaiting an answer, needs no argument, but the following quotation from McCallum (Osler's "Modern Medicine,"

Vol. III., p. 214) is pertinent not only in showing this, but also in showing that the lung invasion is secondary to the pleural invasion. "Whatever the determining cause be, the frequency of primary development of tuberculosis in the apical portions of the lungs is very great, and at autopsy in almost all cases, no matter how advanced, one can generally find traces of the oldest lesion at that point. . . . The apical lesion may undergo cicatrization or extend to other parts of the lung. Probably cicatrization results in a very great number of individuals in whom tuberculosis has never been recognized and thus permanently cuts short the progress of the disease. Such are the cases in which tight adhesions are found between the pleural layers over the apex of the lung and beneath, a rather thin, flattened scar which extends only a short way into the substance of the lung. In other cases there are no adhesions, but merely a scale-like puckered thickening of the pleura at that point, with much gray and black pigmentation, both in the scar and the immediately adjacent lung substance."

The very latest authority on tuberculosis (Klebs, Appleton) has the following: "Among the reasons assigned for the peculiar predisposition of the apical parts to tuberculous localization are the poorer nourishment of these parts, especially at the time of puberty, because the corresponding part of the chest then takes only a very small part in the respiratory movements; it is also held that at the apex the bronchi branch at such angles that obstruction easily occurs." This is very eloquent, but not in solving the problem. The eloquence lies in the desperate character of the alleged explanations.

When Koch announced his discovery in 1882 he startled the whole world, both lay and medical, by proclaiming tuberculosis an "exquisitely infectious disease." Being exquisitely infectious like measles, scarlet fever, whooping cough, etc., we should expect it to be "caught" in childhood just as they are. And so it is, but it has required nearly a full generation for even those in the forefront to realize that tuberculous infection is a disease of childhood. Prior to Koch's discovery no medical doctrine was more firmly established than the one that consumption is hereditary. The fact that the "consumptive diathesis" began so early in life and ran in families furnished excellent reasons for the belief. Baumgarten was so impressed by the great frequency of the disease in early life and its localization in the lymphnodes that he maintained that the bacillus itself is inherited. Behring was so impressed by this early infection that he drew the inference that it was due to the milk diet and promulgated the erroneous dictum that "the milk fed to infants is the chief cause of consumption." So far from this fact of infection in childhood requiring a special explanation, as Baumgarten and Behring seemed to think, it would be remarkable if it were not so. All widely prevalent infectious or contagious diseases are necessarily diseases of childhood except those due to the sexual relations. Smallpox might seem an exception, but before the days of vaccination it was classified with the children's diseases. Theobald Smith says, "tubercule bacilli do not differ from other infectious agents who find their easiest prey in the young." Why, then, have we been so long realizing the obvious truth that tuberculous infection, both by reason of its "exquisitely infectious" nature and the obiquity of the tubercle bacilli, is and must be a disease of childhood? First, because the name itself, which Schoenlein gave it in 1839, is misleading in implying "no tubercles, no tuberculosis"; and, secondly, because we think of tuberculosis as a disease of the lungs and that the bacilli reach the lungs directly through the air. Now actual infection of the lymphnodes may cause such trivial symptoms as to fail to attract attention, or, if attracting attention, are dismissed as scrofula, as though "scrofula" were something different from infection with Koch's bacillus. So much are we influenced by habit and mere names that we still fail to realize, apparently, that the first stage of "tuberculosis" is a lymphnode "tuberculosis," though it may be very difficult or even impossible to find any tubercles in the diseased node.

The age of the greatest morbidity and mortality from pulmonary tuberculosis is that from 15 to 45, with the maximum about midway between. Is this because it is the age of maximum susceptibility to infection? We know directly to the contrary that childhood is the age of maximum susceptibility to infection. The real reason must be sought and will be found in answer to the question, Why are the bacilli, hitherto latent in the lymphnodes, at about the age of 15 better able to get a lodgment on the pleural surface, usually the apical? So beautifully are the workings of the laws of heredity and adaptation designed for the continuance of the species that it is very much as if the bacillus were endowed with reasoning power. The bacillus reaching the lymphnode of a child is content to remain there because it does not wish, so to speak, to reach the lungs yet, for it serves its species best by providing for the infection of the next generation of its host. If it reached the lungs of the child when infection occurs, *i.e.* in childhood, and caused death in the usual period of about two years after invading the lung, the human race would soon be exterminated. Inasmuch as the child, by reason of its susceptibility, must receive the infection, a latent period to bridge over the time until the child itself has reached the age for having children becomes a logical necessity. We now can see the survival value of this latent lymphnode stage. The period from 15 to 45 is the very time when children are being born to parents and are in most intimate contact with them, and from the standpoint of the parasite the most propitious time to be expelled from the lungs. This view furnishes the clue to the real meaning of Louis' law, which reads: "After the age of 15 tubercles do not present themselves in any organ without being likewise seated in the lungs." Louis came to his conclusion long before there was a science of bacteriology, but his law has been confirmed recently by Harbitz of Christiania, who says: "To draw the line at the fifteenth year, as is perhaps most generally done, seems to me more correct, as in regard to morbid anatomy the behavior of tuberculosis before and after this age varies considerably, though naturally there is no sharp distinction." This critical period, the fifteenth year, happens to coincide with the maturing of the sexual organs and the beginning of sexual life. Is it only a coincidence, or is there a causal relation? Let us see. Physiologists teach that the pleural cavity is a large lymph space and its contained serum is properly designated "lymph." If this lymph stream be contaminated with tubercle bacilli they will eventually reach the pleural surface, and we know from the frequency of tuberculous lesions, especially at the apices, found at autopsy, no matter what caused death, that the tubercle bacillus easily gets a

lodgment there, after the age of puberty especially, but does not always succeed in penetrating the pleura and reaching the air vesicles. In spite of the fact that McCallum was so near the truth (*i.e.* that the invasion of the lung is secondary to the pleurisy instead of *vice versa*) he just missed it, as is shown by this: "In all cases of active tuberculosis of the lungs, when the lesion approaches the surface there is involvement of the pleura. In certain cases, however, there is no very conspicuous lesion in the lung." (P.222, *idem.*) If the fact that tuberculosis of the lungs is secondary to pleural involvement is once appreciated it will not be difficult to understand why such a very large percentage of pneumonia and pleurisy cases eventually terminate in phthisis. The bacilli contaminating the serum or lymph which lubricates the pleural surface are usually phagocyted or prevented from getting a lodgment on the pleura when the phagocytes have a chance to attack them in this thin film of lymph. The apex is peculiar in this: It has only its own scant lymph transudate which is immediately carried below by gravity. This effect of gravity will be more pronounced in those with a "peaked" apex. This theory is not contradicted when applied to tuberculosis in cattle as are the orthodox explanations (?), "insufficient aeration, nutrition, immobility," etc. In cattle it happens to be that the caudal lobe is the one first affected, the lobe most active and making the largest excursion. By reason of the fact that cattle go on all fours, with the head low, the caudal lobe happens to be the *highest* point. When I first read of the causing of tuberculosis of the thin border of the cephalic lobes in rabbits by injecting human bacilli into a vein of the ear (Theobald Smith) I was surprised, thinking that as quadrupeds it should have been the caudal lobe as in cattle. But a little reflection and observation of sick rabbits in cages convinced me that the thin border of the cephalic lobes was likewise the *highest* point in these humped over rabbits.

If we needed any further evidence that the pleural surface is usually the primary seat of phthisis it is furnished by the clinical symptoms. That very superior clinical teacher and compiler of textbooks, Dr. Osler, speaks thus: "Cough is one of the earliest symptoms and is present in the majority of cases from beginning to end. At first dry and hacking" (which describes a pleurisy cough). He also says "A dry pleurisy is a very common accompaniment of the early stages of tuberculosis." This theory not only harmonizes with but actually explains why the "peculiar, flat-formed chest with protruding scapulæ in persons with long bones" which constitutes Hippocrates' *phthisicus habitus* is well named.

Laennec, Louis, and many other sagacious clinicians have called attention to the small heart as a predisposing cause of phthisis. In the light of this view the reason is plain: A small heart means low blood-pressure; low blood-pressure means scant flow of lymph, for the transudation of lymph or serum is comparable to the process of filtration where the rate is commensurate with the pressure. It is this fact that makes sexual activity (by lowering blood-pressure) and more especially sexual over-activity a causal factor. The well recognized tendency to sexual intemperance of the consumptive has the relation of cause rather than effect, I opine. Decreased flow of lymph over the pleura enhances the probability of the bacilli becoming "stranded," so to speak, on the apical pleura. A small heart in relation to body weight seems to be the determining factor in susceptibility to tuberculosis of the lungs in the lower animals. Hutchinson has shown that those species prone to it have hearts whose weight is less than 1/100 of the body weight. Thus the deer is almost insusceptible; its heart is 1/90 its total weight. The antelope is very susceptible; its heart is only 1/250 of the body weight. Sheep are almost immune, 1/100. Cows are very susceptible, 1/250. It is known that mitral stenosis is antagonistic, while pulmonary stenosis predisposes to tuberculosis, and the reason is clear in the light of this view. It seems unnecessary to add other reasons for my contention, but I will ask any reader still unconvinced to examine in the light of this view the plate from Koch's original paper, "Die Aetiologie der Tuberculose," beautifully reproduced in the Reference Handbook of the Medical Sciences, and note in Fig. 5 that the bacilli are seen only in the air vesicles lying in immediate contact with the pleura. If he is still unconvinced, I would classify him with that genus which in Harvey's day "preferred to err with Galen than be right with the circulator."

In the interest of brevity and to avoid distracting the reader's mind I have not always named my authority for the *facts* stated; they can be easily verified in any up-to-date medical library, but I acknowledge special indebtedness to Klebs' work. As for the conclusions or generalizations I assume the responsibility.

THE ARC LIGHT IN MEDICINE.

By A. D. ROCKWELL, A.M., M.D.,

NEW YORK.

NEUROLOGIST AND ELECTROTHERAPEUTIST TO THE FLUSHING HOSPITAL.

The therapeutic possibilities and values of physical methods of treatment receive even yet but scant consideration at the hands of the profession at large. Because of this lack of appreciation many a case of acute or subacute congestion—or, as it has been aptly termed, blood stasis—merges into the chronic stage, when by proper physical treatment in the beginning prompt recovery might have followed, and chronic conditions, which active physical methods would resolve in much quicker time, run a tedious course of years or become hopelessly chronic. I propose, therefore, in this paper to discuss briefly physical methods in general and the arc light in particular. It is said that every herb of the field possesses certain therapeutic properties, which if rightly directed may prove of value in the treatment of disease. Be this as it may, there is no question but that every physical energy is capable of playing an important part in the restoration and conservation of physical and mental well being.

Heat, electricity, vibration, light, and indeed not alone light, but every individual constitutent of the solar spectrum, visible and invisible, have each a special physical and physiological activity. How to differentiate between these many manifestations of physical energy and select the one best adapted to the case in hand is one of the most difficult, as it is the most neglected, question of physical therapeutics. One reason for this difficulty is the fact that all these agents or manifestations of force have very much in common in the effects they produce. The broad, fundamental idea first suggested by the writer in conjunction with Dr. Beard many years ago—that electricity is not a mere stimulant, useful only to quicken the activity of paralyzed

muscles, but a powerful aid to nutrition, distinctly affecting the excretory and secretory bodily functions—applies with equal truth to others of nature's forces. Heat and light and the individual actinic rays that go to make up the latter all possess the ability under certain conditions to energize the bodily activities. It is this very similarity of action that enhances the difficulty of differential selection, for every physical force is simply a mode of motion, a form of vibration, and its character and effect depend upon the frequency of these vibrations. A slow rate gives us sound. Increased frequency develops the thermic sense until, with infinite rapidity of vibration, light, the visible spectrum, appears, merging again as the frequencies increase into the invisible, where only chemical means, and not the senses, detect the presence of the ultraviolet and the *x*-rays. One of the most important effects of physical methods of treatment, as all must agree, is the dissipation of local congestion or blood stasis.

Massage does it, and unquestionably much of the success of osteopathy is due to this. There is no form of electricity, faradic, galvanic, static, or high-frequency, that has not time and again given evidence of its power in this direction, and treatment with the ordinary vibratory apparatus does the same thing. It is this power to remove local congestion, to stimulate nerve and muscular fiber, and thus hasten and correct the excretory and secretory processes of the body (constructive metabolism) that gives to well-directed electrical applications their well-known efficiency. I should say, therefore, that electricity, manifesting itself in so many forms, each differing so widely from the other in its physical and physiological effects, has perhaps a wider range of usefulness than any other individual physical agent.

This seems to me a reasonable deduction after many years of study and practice in this department of therapeutics. The secret of success depends upon a thorough knowledge of the differential indications for its use, and a skilled technique in the administration of its various forms. Notwithstanding these many years of fairly satisfactory experience in the use of electrical methods, I am, nevertheless, in these later days, beginning to feel the necessity of emphasizing the superiority of phototheraphy in the treatment of certain bodily aliments. Phototheraphy, strictly interpreted, would apply only to the rays of the visible spectrum, but in a more liberal sense are included the combined luminous, calorific, and actinic rays. It is readily seen, therefore, that the term phototherapy as applied to the far-famed Finsen method is a misnomer, since the ultraviolet rays, isolated and made effective at such infinite trouble and expense, are not included in the visible spectrum.

It may not be inopportune here to correct the persistent misapprehension as to the function and effect of the violet and ultraviolet rays; the first of so little importance as an individual entity, and the latter so valuable and yet so restricted in its therapeutic application. Even among medical men this misapprehension is found, and the laity, not a few of them, speak of the violet rays as of some mysterious agent of magic power. While the ultraviolet rays readily destroy germs with which they come in contact, yet unfortunately the blood and the outer layers of the skin act as barriers to deep penetration, and, therefore, to get his memorable therapeutic effect in the treatment of a certain malignant disease (lupus), Finsen not only filtered his ultraviolet rays, but was compelled to devise a method for completely dehematizing the superficial tissues in order that the rays might penetrate. Light treatment, or phototherapy, is no new thing; it is indeed as old as the history of man, for wherever there was sunlight, there also was the opportunity for treatment. Sunlight, the arc light, and the incandescent light—these are the three methods that are utilized in therapeutics. Sunlight being nature's method, one might say it was the ideal method. And for a long race this is true, sunshine, pure air, and good food being the active trinity for the creation and preservation of health. In another sense, however, it is not true. Sunlight is capricious, often not obtainable when wanted, and is far less controllable than the artificial forms of light, which can instantly be made intense or mild, concentrated or diffused, and even the different rays selected or excluded at will. As between the two forms of artificial light, the arc or the incandescent, I have no hesitation in recommending the former, from the fact that a considerable experience has convinced me that with the former one can accomplish all that is possible with the latter, and more. In the nomenclature, the incandescent light might be called "radiant light," since the arc light is the true "radiant energy," and in this paper will be so designated. This is so because the arc light, like the light of the sun, includes the rays of the spectrum complete, while the incandescent light is deficient in its actinic rays.

This vital principle of light in connection with heat is what differentiates phototherapy, as illustrated both by the incandescent and arc light, from other physical methods, while the arc light, with its chemical rays, stands alone as the actual and complete radiant energy. As radiant energy the arc light possesses advantages over other physical methods. It not only relieves congestion or blood stasis as do these, but in greater degree accelerates natural oxidation as manifested by increased elimination of carbon dioxide. More important still, perhaps, true radiant energy, as is clearly demonstrated, increases the hemoglobin-carrying power of the blood, thus rendering it of great value in all anemic conditions, while its bactericidal properties are pronounced. He who has been permitted to observe the really remarkable effects of radiant energy in certain pyogenic processes needs no other argument to be convinced of its value.

But without attempting laboriously to develop the therapeutic rationale of the arc light, or tire the reader with illustrative cases, a few of which I am sorely tempted to relate, I will simply indicate a few conditions where some of its best results are seen, and offer a few words along the line of the technique of its application. In naming these individual conditions I shall speak not from hearsay, but shall refer to those only in which I have had a sufficient personal experience to enable me to speak with some degree of authority.

Relief of pain is one of the great and paramount objects of medical service, and in radiant energy we have at our command a most efficient aid. In neuritis we have pain in its most severe and obstinate form, and it is in neuritis, perhaps, that the best results of radiant energy are observed. I have seen cases that have suffered for months without relief, excepting the temporary alleviation afforded by drugs or topical applications, relieved of all their sufferings for a considerable length of time by a single sufficient exposure. It is not to be

understood that in the majority of cases such remarkable results are seen, but such cases do occur, and help to illumine the dark path of human suffering. Only recently one unfortunate who had exhausted the resources of medicine and local applications, chanced to experience the almost immediate relief following the light treatment and exclaimed: "Why have I had to suffer so long with such a method available?" In no condition are the beneficial effects of light more pronounced—and here both the arc and incandescent act equally well—than in obstinate forms of lumbago. It produces effects as immediate as any electrical method, and in my experience the results become more quickly permanent.

It would not perhaps occur to the uninitiated that chronic bronchitis might be an inviting field for the action of radiant energy. Reflection, however, should suggest its adaptability, and in a number of cases I have been enabled to satisfactorily demonstrate its value. The results are not rapid, except as temporary comfort is afforded, which is often quite marked, but persistent effort has in several cases been followed by more or less complete recovery. It ought not to be difficult to understand how or why the combined luminous, calorific, and actinic rays of light in concentrated form should be the very best agent for the relief of certain forms of chronic respiratory disease. It has been claimed that this method of treatment has great value even in tuberculosis. I regret that my experience does not extend so far, but I can well believe it, and hope that in some way and some time it may be thoroughly tested.

For the relief of the symptoms of high arterial tension, both radiant energy and the electrical method termed autocondensation are unquestionably of value. I have had experience with both and have frequently witnessed the lowering of pressure and the consequent symptomatic relief afforded by either method. A fact of no little importance in the treatment of arterial sclerosis is that no undesired depression of the heart's action follows. To what extent any curative action may follow the use of these methods in actual arterial sclerosis no opinion is attempted, but their power to control circulatory activity should render them of value in the earlier stages, and their use should go hand in hand with other and accepted methods.

In dermatology, phototherapy, or radiant energy, rather, is a valuable and too neglected remedy. As in the cure of lupus it is the ultraviolet ray that is the efficient agent; so, too, in the more common and nonmalignant forms of skin disease, but fortunately it is not necessary as in the first condition to eliminate the heat rays in order to concentrate a sufficient strength of the ultraviolet. Indeed, the powerful light rays and the heat rays as well, if not too intensely focused, probably add to the efficiency of the treatment. The incandescent light is of far less value, if not practically useless, in the treatment of skin diseases, but the arc light with electrodes made up with a combination of carbon, magnesium, and iron is powerfully germicidal, and its destructive influence over pathogenic bacteria is seen in its power to limit the suppurative process and thus abort the development of abscesses.

While I have had no very large actual experience to confirm the strong theoretical considerations for its use in dermatology, I can yet point to a case of scrotal eczema, several of herpes zoster, one of acne rosacea, and several obstinate and rather suspicious cases of epithelial disease where the results have been good. It is a wonder to me that dermatologists do not evince a more distinct appreciation of their loss in neglecting this method of treatment.

There are a few points in technique in connection with the administration of radiant energy quite essential to success. While the individual frequencies are important, the ultraviolet for superficial action, the blue and others for deeper effects, yet it is the complex of radiant light energy upon which one must depend for all around therapeutic effects. In order that the light should be as rich as possible in chemical rays the electrodes must be of the purest carbon combined with magnesium, potassium, and iron, which give off the maximum of ultraviolet, violet, or blue radiations. As a reflector glass is far better than metal, since the reflecting surface of the latter soon becomes impaired and loses more or less of the concentrating power. The apparatus should be so constructed that the rays can be adjusted at will, giving either an intense convective heat or heat more diffused and milder. An important point in connection with this method of treatment, especially in neuritis and the relief of pain in general, relates to the length of the light exposure.

Time and patience are essential. The brief séances sometimes recommended are inefficient. Exposure should seldom last less than one-half hour, and not infrequently a much longer sitting is desirable. Especially is this the case when the area to be treated is large and irregularly located. While in the administration of the arc light there are no *x*-ray effects to be dreaded, as seems to be the fear of some patients, yet care is to be exercised in its use, particularly in low nutritional conditions. Here it is quite easy by a too liberal use of convective heat, aided by the chemical effects, to produce a local sore. Unlike *x*-ray effects to be sure, healing takes place rapidly enough but it is an unnecessary result and should be avoided.

THE ELECTRICAL TREATMENT OF ARTERIAL HYPERTENSION.

By JOHN H. BURCH, M.D.,

SYRACUSE, N. Y.

ELECTROTHERAPEUTIST AND RADIOTHERAPEUTIST TO ST. JOSEPH'S HOSPITAL, THE SYRACUSE HOSPITAL FOR WOMEN AND CHILDREN, AND THE SYRACUSE FREE DISPENSARY.

That a man is as old as his arteries is a trite but true clinical aphorism. Arterial degeneration is the most frequent cause of death. In fact, the contributory or direct cause of the majority of mortalities after fifty years of age results from degenerative changes within the walls of the blood-vessels. As the vast majority of arterial degenerations are accompanied by, and as a rule preceded by, arterial hypertension, we are able by means of the modern blood-pressure apparatus to forewarn ourselves of the impending danger and seek measures to prevent the insidious advance of general arterial fibrosis.

There are three factors that enter into the study of arterial hypertension that are very important from a therapeutic standpoint: (1) the ventricular systole; (2) the peripheral resistance; and (3) the elastic recoil of the arteries. Anything that impedes the current of blood after it leaves the left ventricle offers peripheral resistance. This may

result from contracted kidney, narrowed or obliterated blood-vessels, friction, or gravitation. In the great majority of incipient cases, however, this peripheral resistance is the result of vasomotor constriction due to toxins, various reflexes, and psychic influences that stimulate vasomotor contraction of the peripheral blood-vessels. If the elastic recoil of the arteries is not impaired, it can readily compensate for this increased peripheral resistance, and push the column of blood onward through the contracted vessels with a force almost equal to the ventricular systole. If this power of recoil of the arteries is lost or impaired, as it is in true arterial fibrosis, the walls of the blood-vessels impede rather than help the flow of blood. We have left then the power of the ventricular systole to overcome both of these opposing forces. To accomplish this, the heart muscle becomes hypertrophied to meet the increased demands put upon it. So long as it can compensate for this increased peripheral resistance and deficient arterial recoil a fair standard of health and well-being may be maintained. Sooner or later, however, we may expect myocardial or coronary arterial degeneration that will break also the ventricular compensation. When the cardiac compensation gives way, nature may make one more effort to restore for a time compensation. This is done by vasomotor constriction of the arterioles, thereby increasing peripheral resistance. When this event occurs we are dealing with a latent break in compensation that may not be made manifest. From a therapeutic standpoint this is most important, as great harm may be done in these cases by the forcible reduction of the arterial tension.

From this it will be seen that it is very important to determine the actual state of compensation before attempting to reduce blood-pressure. This may be done in several ways. Normally, there is a difference of from five to thirty millimeters in the blood-pressure when taken in the recumbent and erect posture. If there is vasomotor insufficiency, it will be found that the arterial tension will not be proportionately greater as it should be when taken in a standing position. If this is due, as it generally is, to splanchnic vasomotor ataxia due to enterotoxins, by forcibly supporting the abdominal viscera by traction upward upon the abdomen, it will in a few moments cause the arterial tension to again rise in the standing position.* The same result may be achieved by forcibly concussing the spinous processes of the first, second, and third lumbar vertebræ. This will cause a vasoconstrictor reflex of the splanchnic vessels, thereby augmenting peripheral resistance. If cardiac compensation is broken there will be a rise of arterial tension in the standing position. If the arterial recoil is impaired, there will be but little difference in the standing and recumbent posture.* If we first take the blood-pressure in a sitting posture, and immediately have the patient inhale from a bottle sufficient amyl nitrite to cause a blushing of the face, it will be found that there will be a momentary drop in the blood-pressure to be immediately followed by a rise of systolic pressure of from three to five millimeters. If, in place of an elevation of the blood-pressure, we get a distinct fall, it is pretty certain that we have failing ventricular compensation. If there is no change in the arterial tension after the inhalation of the amyl nitrite, it would prove impaired arterial recoil and probably arteriosclerosis or fibrosis, but it would also indicate that the ventricular compensation was not broken and benefit might be expected from lowering the peripheral resistance. If, on the other hand, after the administration of the amyl nitrite the blood-pressure rapidly falls, causing more or less depression, we may know that it is best not to interfere with the peripheral resistance, that is, trying to compensate for a broken ventricular compensation.

I have of late been utilizing a method that bids fair to be of considerable value not only in the diagnosis of cardiovascular compensation, but also in the treatment of some forms of high arterial tension as well. In studying the effect of electrical currents of high voltage and frequency in the reduction of high blood-pressure, a rather curious phenomenon was observed. If some of these patients with very high arterial tension were subjected to almost any form of electrical discharge from a high voltage source of electrical energy, it was noted that the blood-pressure would rapidly fall from ten to thirty millimeters during a séance of ten minutes. In other cases there would be but a very slight fall, and in a third class of cases there was no change at all. In testing these cases the patient was seated in a chair upon an insulated cushion that was placed upon a plate of metal that was attached to one extremity of a Tesla coil, while the subject held a small hand electrode that was connected to the other extremity of the apparatus. The output of this apparatus was only from twenty to fifty milliampères. If the patients who were not affected by this method were connected to a small d'Arsonval solenoid in the same manner and subjected to a current output of from 200 to 800 milliampères, there was a very appreciable drop in the blood-pressure. If the patients who manifested but a very slight change in the arterial tension when connected to the Tesla coil were subjected to the discharge from the more powerful transformer there would be in almost every instance a very marked fall in the blood-pressure that was at times rather alarming, as it seemed to cause symptoms of collapse that in several instances continued several days. It would seem, therefore, that when the blood-pressure is rapidly reduced by means of a very mild discharge from the terminals of a Tesla coil we are simply dealing with increased peripheral resistance of presumable vasomotor origin.

If, on the contrary, these weaker currents will slightly affect the arterial tension we are dealing with a case of broken cardiac compensation that had better be left alone. In fact, my experience has taught me that it is dangerous to subject these patients to electrical currents of high voltage and ampèrage. Those in the remaining class of cases, that are not at all affected by the discharge from the small output of the Tesla coil, we may safely assume are suffering from imperfect elastic recoil of the blood-vessels and increased peripheral resistance. It is in this class of cases, in which there may, or may not, be true arterial degeneration, that much may be hoped for from electrical treatment. In these cases the cardiac compensation is not impaired, and by relieving peripheral resistance the heart is saved an immense amount of labor and the walls of the blood-vessels are spared the excessive effects of friction. But the effects of these electrical discharges are not confined to the reduction of blood-pressure. The processes of metab-

*Abrams: "Spondylotherapy."

olism are increased as well. There will always be noted an increase in the amount of urea excreted, the quantity of urine voided during the twenty-four hours will be augmented, and there will be also an increased amount of urates excreted. The reduction of high blood-pressure by means of these powerful electrical discharges is also more permanent than by any other method of treatment with which I am conversant. I wish to briefly report two cases that are typical of what may be expected from this method of treatment.

Case I.—Mrs. M. J., aged 54 years, was told by her physician that she was suffering from organic heart disease and high blood-pressure. She had an unstable neurotic temperament and this inadvertent diagnosis plunged her at once into a state of cardiac neurasthenia. An examination revealed an old systolic murmur that was very well compensated for. Her blood-pressure was found to be 200 millimeters with hard and tense arteries. She suffered from insomnia and polyuria. An examination of a twenty-four hours' specimen of urine revealed a total quantity of 60 ounces; no albumin or sugar; specific gravity 1015; urea 2 per cent. In this case we seemed to have only peripheral resistance to contend with. After the first séance of fifteen minutes by means of autocondensation from the terminals of a Tesla coil with a current output of but 60 milliampères, the blood-pressure was reduced thirty millimeters. Three days later it was 180 millimeters. The next treatment reduced it to 160 millimeters, and the next to 150 millimeters, where it remained. She received six treatments. Six months later the patient was examined, the blood-pressure being 150 millimeters. She had ceased to worry about her heart and high blood-pressure, and was able to sleep at night. The question may be raised in this case that the results were largely psychic. This I am willing to admit. It is difficult to eliminate the psychic element from any system of therapy, and I see no just reason why we should.

Case II.—Mr. V., aged 65 years, occupation manufacturer; he is a man of excellent habits, free from syphilis, has never used alcohol, and smokes but three cigars daily, which has been his limit for many years. He has worked very hard during his whole business career and has allowed himself but little recreation. His health has always been excellent. Several years ago he observed that slight annoyances connected with his business disturbed him very much. He suffered from insomnia, became irritable and annoyed over trifles, was compelled to void his urine once or twice during the night, and was particularly annoyed from failing memory. One year before he consulted me he began to experience paroxysmal attacks of pain in his left arm. The pain was very intense, necessitating him to assume a sitting or recumbent posture during the seizure. It was for this pain that he consulted me, as he thought he was suffering from rheumatism. His face was puffy, his lower eyelids edematous, and the arcus senelis well pronounced. An examination revealed an increased area of cardiac dullness, the apex depressed downward, and an accentuated aortic second sound. The lower border of the stomach was on a level with the umbilicus with evidence of general visceroptosis. The pulse was hard and unyielding. The blood pressure was 220 millimeters, Janeway apparatus. An examination of a twenty-four hours' specimen of urine revealed: quantity 60 ounces, specific gravity 1010, urea 1.05 per cent. No albumin or casts were found. In the treatment of this case the usual dietetic and hygienic management was advised. He was first subjected to the secondary discharge from a Tesla coil that had no appreciable effect upon his blood-pressure. From the fact that autocondensation from this source failed to lower his arterial tension, I felt assured that his cardiac compensation was not as yet impaired and that the elasticity of the vessel walls was at fault as the result of degenerative changes. At his next visit he was seated upon an insulated cushion that was placed upon a metal plate. This plate was connected to one extremity of a small d'Arsonval solenoid. The patient held in his hand a small metal electrode that was likewise attached to the spiral. The current was gradually turned on until the meter registered 500 milliampères. Duration of séance was ten minutes. The first treatment reduced the blood-pressure fifteen millimeters. The treatments were continued three times weekly for two months. At the expiration of this period the blood-pressure was 160 millimeters. The amount of urea increased from 1.05 to 1.08 per cent. After the fifth treatment the pain entirely disappeared. I last saw this patient July 12, 1909. He recently wrote to me, however, stating that he had no pains since discontinuing the treatments, and that his physician informed him that his blood-pressure was from 150 to 165 millimeters.

My experience has taught me that these two cases are typical of what may be expected from electrical treatment of arterial hypertension. I have also been impressed in the treatment of these cases by the fact that most of my cases have been active business men of most exemplary habits. Very few of these cases were alcoholics, syphilis was in nearly every instance excluded as an etiological factor, and in only a few cases was tobacco used to excess. It would seem, therefore, that mental anxiety, worry, the strenuous life, the monotonous treadmill existence, together with overindulgence in eating, too little recreation and exercise, were responsible for the great majority of these cases of arterial degeneration.

VACCINE THERAPY IN ACUTE RHEUMATIC POLYARTHRITIS.

By W. C. WOLVERTON, M.D.,

LINTON, N. D.

While the specific causative influence of *Streptococcus pyogenes* in acute rheumatic polyarthritis is not universally admitted, many things point to its being at least the predominant factor, either as the true etiological agent or as being present in a mixed infection. From the experience of others, as well as from personal observations, the writer has been led to the conclusion that the streptococcus is the causative agent in at least the majority of cases; and since beginning the use of streptococcus vaccines in the treatment of this disease, the response has in every case been so prompt that it has had the appearance of a "therapeutic test."

Guttmann, Colin, and Sahli[1] have found what appeared to be a staphylococcus in the articular exudate of patients suffering from acute rheumatic arthritis. Netter[1] found the streptococcus in a large number of cases. Singer[1] has examined ninety-two cases, and found streptococci and staphylococci in a large majority of the cases, and also

post-mortem. Triboulet and Coyon[2] have found a Gram-positive diplococcus, sometimes associated with a bacillus, in all cases examined by them. Acute articular rheumatism is named by French[3] as among the complications and sequelæ of erysipelas, itself known beyond peradventure of doubt to be caused by streptococci. Walker and Beaton[3] concluded that the disease is caused by a specific micrococcus, possibly identical with that first described by Popoff.[3] Poynton and Payne[4] inoculated rabbits with the diplococcus obtained from the arthritic exudate from cases of rheumatic polyarthritis, and succeeded in producing polyarthritis, cardiac valvulitis, and choreiform movements. Beattie[5] describes a Gram-positive coccus, occurring in pairs or short chains, either when seen in tissues or in cultures; in milk bouillon chain formation is more pronounced; intravenous injections cause polyarthritis, endocarditis, and chorea; subcutaneous injection, even in large dosage, does not cause suppuration. The streptococcus is always found on the heart valves in ulcerative endocarditis, according to Zapfe,[6] Menzer, and also Singer and Meyer[7] regard the streptococcus as the infective agent and the oral cavity as the portal of entry. Birch-Hirschfeld, Bouchard, and Charrin,[8] Triboulet, Sahli, and J. Sacaze[8] reaptedly found streptococci and staphylococci in the synovial fluid of the articulations, in the pericardial fluid, and on the cardiac valves in cases of acute and subacute polyarthritis.

In many cases, when cultures from cases of polyarthritis have produced cocci of the diplococcic or staphylococcic type, there has been a question as to whether the organisms were not really streptococci, which under unfavorable cultural and environmental conditions thus manifested evidences of pleomorphism. Certainly the severity of the disease would point to streptococci rather than staphylococci as the etiological agent.

Several instances have occurred in the writer's practice which have convinced him of the specific causative influence of the streptococcus in acute rheumatic polyarthritis. Some five years ago he was called to see a German-Russian woman who had a severe case of facial erysipelas. A nephew, visiting his aunt during her illness, contracted a streptococcus lymphangitis of the arm. A little niece of this woman, living in the same house with her aunt, had a very virulent attack of acute polyarthritis, complicated by endocarditis. In another group of cases a German-Russian farmer had an acute polyarthritis of both ankle and wrist joints. His brother visited him and was attacked by the same disease. A child of this brother shortly died of what was apparently peliosis rheumatica. Two young sons of the first man became ill, one with acute osteomyelitis of the lower end of the tibia, in which streptococci and staphylococci were present: the other with a streptococcus infection of the skin of the leg, with vesicles and blebs containing streptococci. The first man and his sons received streptococcus vaccine and promptly recovered. The second man is slowly recovering, after a two months' illness, and his child died; neither of these two latter received the vaccine treatment, but got sodium salicylate.

Dissatisfied with the salicylate treatment, I began in January, 1911, the routine use of streptococcus vaccine in such cases of acute rheumatic polyarthritis as were met with in my practice, with results as found in the following case reports:

Case I.—A. N., æt. 28, male, German-Russian, farmer. First seen January 18, 1911; had then been confined to bed eight days. Both ankles, knees, and wrists affected. Bad mitral valve lesion from previous attack two years before. Coughing considerably and complaining of substernal pain and oppression. I had with me a mixed vaccine containing 20,000,000 streptococci and 30,000,000 pneumococci, with which the patient was inoculated. At the time the vaccine was injected the patient was unable to move a limb, in fact was entirely helpless. When he was again seen, twenty-four hours later, he could toss his arms and legs about with almost no pain at all, and was sitting propped up in bed. In forty-eight hours from the time of the first inoculation the patient, although contrary to orders, sat up in a chair most of the day, and no ill effects followed. Within a week he was walking about, free from pain. On January 23 a second (and last) dose of vaccine, containing 30,000,000 streptococci, was given. This completed the cure, and there has been no recurrence to date. Capsules, each containing aspirin, 0.50 gm., were left for this patient at the time of the first visit, but he took only one or two of them, and promptly vomited them. No other medication was used, except digitalin and strychnine, for the valvular trouble. The results attained here were so striking that I resolved to give the streptococcus vaccine further trial in similar cases.

Case II.—F. W., æt. 27, male, German-Russian, farmer. First seen February 6, 1911. This patient had an involvement of one ankle, both wrists, and one shoulder, and was unable to turn in bed without help. There was no cardiac involvement. When I first saw him the patient had been getting large doses of sodium salicylate for sixteen days, with conditions growing steadily worse. He was inoculated February 6 with 30,000,000 killed streptococci. Internally he received aspirin, 0.50 gm.; *q.* 3 *h.*, and elixir of iron, quinine, and strychnine, 4 c.c., *t.i.d.* Locally a solution of menthol guaiacol, and methyl salicylate was applied to the inflamed joints, which were then wrapped in cotton. The patient was again seen February 9, when he stated that within twenty-four hours after the inoculation he could move about in bed without help, and that the pain had almost completely disappeared. On this date (February 9) 60,000,000 killed streptococci were injected. The patient was seen for the third time on February 12, at which time he was able to walk about, and was practically well; but as a precautionary measure an inoculation with 60,000,000 streptococci was given. No further trouble nor recurrence.

Case III.—L. C., æt. 5, male, American. Seen April 7, 1911, at which time he had been very ill three days. Both ankles badly involved. No cardiac lesion. Inoculated with 30,000,000 killed streptococci. Aspirin, 0.35 gm., *q.* 3 *h.* also ordered, but the order was not faithfully carried out. No change in the patient's condition during the first twenty-four hours; but improvement began at the end of thirty hours, and in forty-eight hours the boy could walk. No relapse or recurrence.

Case IV.—J. O., æt. 30, male, German-Russian, farmer. First seen May 21, 1911, on second day of attack. Ankles and wrist-joints severely involved. No cardiac lesion. Inoculated with 60,000,000 killed streptococci. Internally he was given acetylosalicylic acid, 0.50 gm., *q.* 2 *h.*, and a

single dose of 0.33 gm. phenolphthalein. I told the patient, who lived twelve miles from town, that I would call again on the 24th and administer a second dose of vaccine; but on that date received word that I need not go, as the patient was walking about outdoors. May 29 the patient received a second inoculation at the office as a preventive measure.

Case V.—W. W., æt. 32, male, American, physician. This patient was the writer himself. I was caught out in a heavy shower, and a day or two later the right shoulder and, to a less extent, the right hip were involved. Aspirin, 0.50 gm., *q.* 2 *h.*, was taken, but the trouble grew worse. Next day, July 5, 1911, 60,000,000 killed streptococci were injected at the insertion of the right deltoid. On July 6 I was able to attend to my practice; whereas I had been confined to bed on the 4th and 5th.

Case VI.—L. B., æt. 6, female, German-Russian. Seen July 7, 1911. Both ankles involved for two weeks or more; sometimes could walk, sometimes confined to bed. Inoculated with 30,000,000 killed streptococci. Internally was given aspirin, 0.33 gm., *q.* 3 *h.* Tablets containing reduced iron, mercury bichloride, strychnine, and arsenic trioxide were also given, because of coexisting anemia. This patient was not seen again, but made a recovery within three or four days.

Six cases do not form a large series from which to draw conclusions; but they were all of a very severe character, and the response to the exhibition of *Streptococcus pyogenes* vaccine was in every case so prompt and satisfactory that I have felt impelled to report the cases and to urge others to give the remedy extensive clinical trial. Moreover, in at least four of the six cases, the salicylate treatment was not followed; and in two cases the patients grew worse in spite of faithful adherence to salicylate treatment. So the uniformly good and prompt results must be ascribed to the vaccine. In every case the temperature quickly fell, there was a rapid cessation of pain and disappearance of signs of inflammation. The patients, moreover, remarked a feeling of exhilaration, or stimulation, which came on in from three to forty-eight hours after the inoculation. In no case was there any evidence of a harmful negative phase. In none of the six cases above reported did any cardiac valvular lesion develop subsequent to the employment of the vaccine.

Considering the unsettled nature of the question as to the specific etiological microorganism in this disease, it seems not unwise to the writer to employ a mixed vaccine, containing *Streptococcus pyogenes* and *Staphylococcus aureus et albus*, rather than the streptococcus alone. However, the plain streptococcus vaccine used in the cases reported above left nothing to be desired.

The vaccines employed in the treatment of these cases were all "stock" vaccines, made from several strains (at least six, I believe) of streptococci, obtained from various cases of streptococcic infections.

THE ALBUMIN REACTION OF THE SPUTUM IN PULMONARY TUBERCULOSIS.

By MAURICE FISHBERG, M.D.,

AND

DAVID FELBERBAUM, M.D.

NEW YORK.

The chemical examination of the sputum in diseases accompanied by expectoration has not been pursued with the same zeal as cytological and bacteriological investigations. Some sixty years ago Biermer published a monograph in which he gave a thorough description of the chemical reactions of the sputum in various pathological conditions. He found that in chronic bronchitis the amount of mucin and sodium chloride is considerable, while extractives are found only in traces, and albumin is not found at all. In pneumonia, in addition to the mucin, there are also albumin and blood pigment. It was Biermer's opinion that the sputum in pulmonary tuberculosis is of about the same character as that of chronic bronchitis, while in cases of pulmonary edema it is rich in albumin and water and poor in mucin. Another paper on the chemistry of the sputum is that of Wanner, who was first to emphasize the diagnostic importance of the albumin reaction in cases of pulmonary tuberculosis, and who showed that it is found in most cases of inflammation of the parts from which the sputum is derived. He insisted that albumin is never found in cases of uncomplicated chronic bronchitis, while in pulmonary tuberculosis an albumin reaction is never absent. Similarly in cases in which there is doubt as to the diagnosis between pneumonia and pulmonary infarction, the presence of albumin in the sputum, provided there is no admixture of blood, speaks in favor of pneumonia.

Besides these two monographs we know of very little of importance in medical literature on the significance of albumin in the sputum until some two years ago Professor H. Roger of Paris again took up the problem and published several papers, in which he arrived at the conclusion that the albumin reaction of sputum, when found, is of great diagnostic importance. From the chemical standpoint, Roger divides sputa into two great groups: The first gives no albumin reaction; it is a secreation more or less abundant in cases of simple bronchitis, acute or chronic, and pulmonary emphysema uncomplicated by dilatation of the heart. The second group of sputa contain albumin and are found in graver pathological processes of the respiratory tract, due either to inflammations or exudations, and never occurring in simple bronchitis. In the large number of cases often met with by every practitioner, in which the differential diagnosis between bronchitis and pulmonary tuberculosis is difficult, the presence of albumin in the sputum decides in favor of tuberculosis. Roger, however, insists that while the absence of albumin in the sputum positively excludes tuberculosis, its presence is no positive indication of the disease, because albumin may also be found in the sputa of cases of pneumonia, pleurisy, edema of the lungs, pulmonary emphysema with dilatation of the heart, etc.

In this communication we submit a report on the results of the chemical examination of the sputum in cases of pulmonary tuberculosis in the wards of the Montefiore Home. Many of the cases have

been in this institution for several years, one even as long as twenty-four years, so that the diagnosis, if made, is quite reliable. They were all in the advanced stage of the disease. One of us (Fishberg) has also examined chemically the sputum in cases of incipient and moderately advanced cases, but their number is as yet not large enough to enable us to include these cases in this communication. These cases will be reported in a subsequent paper. In addition we have also examined for albumin in the wards of the Montefiore Home several other cases which have been placed at our disposal by the medical director, Dr. S. Wachsmann, to whom we take the opportunity to express our gratitude.

Each specimen of sputum was first examined microscopically for the presence of tubercle bacilli by the usual method, *i.e.*, the Ziehl-Nielsen stain. In some cases the antiformin test was used for corroboration. The determination of the presence or absence of albumin was made in the following way: A 3 per cent. solution of acetic acid was added to the sputum with the object of coagulating the mucus, and the mixture was then thoroughly shaken. It was then allowed to stand for ten or fifteen minutes, and then again shaken repeatedly. The contents of the sputum bottle was then filtered and the clear filtrate was collected into a test tube in just sufficient quantity for the test. This clear fluid was boiled over a Bunsen burner, and while boiling a concentrated solution of salt was added drop by drop, or crystals of sodium chloride were thrown into the solution. If albumin is present there results a curdy precipitate which, on standing, settles to the bottom of the tube. The amount of the precipitate depends on the amount of albumin present. Nothing but a curdy precipitate is considered as positive, because the presence of mucus, which the acetic acid does not always coagulate completely, may also give a cloudy precipitate on boiling; but this reaction is not curdy, nor does it settle on standing.

On the whole, our results do not confirm Roger's statements to the effect that in every case of tuberculosis the sputum gives a positive albumin reaction. We found some cases of undoubted tuberculosis in which careful analysis of the sputum gave negative results. In forty-two specimens of sputum showing the presence of tubercle bacilli, the albumin test was also positive. It has been our experience that the number of bacilli present in the field has no relation to the amount of albumin found by the chemical test. Some specimens of sputum showing an enormous number of bacilli had only a faint trace of albumin, which was sometimes so slight as to render it altogether doubtful whether the reaction was positive. One thing, to which we shall again revert, must be mentioned. It appears that the activity of the process has considerable influence on the intensity of the chemical reaction. In active, progressive cases the amount of albumin is greater than in quiescent or healing cases. In fibroid cases the amount is often infinitesimal, or entirely absent, as we shall soon show in detail.

Three cases of tuberculosis, with bacilli in the sputum, which gave negative results at the first examination for albumin, reacted positive at a subsequent one. They were all in the advanced stages of the disease, and one of these has even been a sufferer from chronic nephritis which has troubled him very much. But the lesion in the lungs in all these three cases was rather quiescent, the fibroid changes being quite marked. Seven cases of unquestionable tuberculosis, but in which tubercle bacilli were not found when the sputum was examined, gave a positive albumin reaction, two only faintly. There were three cases of tuberculosis under observation at the institution for some time, so that clinically there was no doubt as to the correctness of the diagnosis, in spite of the negative results both bacteriologically and chemically.

There were also three cases of tuberculosis, with tubercle bacilli in the sputum, and the very specimen giving positive results bacteriologically reacted negatively as regards the albumin reaction. One of these was a case of abdominal malignant growth with general metastases (confirmed by autopsy) and with a complicating pulmonary tuberculosis, as was evident from the large number of tubercle bacilli in the sputum. It may be that the fact that the tuberculous process was rather acute, at the terminal stage of the patient, was the cause; because, as Roger states, the sputum in acute miliary tuberculosis often gives a negative albumin reaction. But the other cases are more interesting and will be given in detail below.

Of the cases of pulmonary emphysema examined, two gave a positive albumin reaction and three were negative. Of five cases of bronchial asthma the sputum was negative in all, while one case of asthma complicated by emphysema and cardiac dilatation reacted positively. The sputum was also positive in two cases of Pott's disease.

Analyzing the results, we find that the albumin reaction is undoubtedly obtained in the vast majority of cases of tuberculosis, but our investigations do not bear out the statement that every case of tuberculosis gives a positive albumin reaction. On the other hand we have found the chemical test of decided value in some doubtful cases, as can be seen from the following details:

Case I.—W. H., aged 54, salesman, was admitted to the institution for severe trifacial neuralgia. His father died of pneumonia; otherwise his family history was of no importance. He had measles and scarlet fever during infancy, pneumonia at the age of 25, and several attacks of influenza. Twenty-nine years ago he sustained a fracture of the lower jaw and has ever since suffered from facial neuralgia. In 1905 he had an attack of grippe and since then has been coughing. He has had no fever, no night sweats, nor any pulmonary hemorrhages, and he has sustained no loss of weight, while his appetite has been fair. Repeated examination of his sputum for tubercle bacilli was negative. But a chemical examination of the sputum made August 3, 1911, gave a positive albumin reaction. Physical examination shows a rachitic chest with kyphoscoliosis, dullness over the right apex, bronchial breathing over the first and second right interspace, but no adventitious sounds.

Case II.—M. P., house painter, aged 40. Family and previous history negative. Had grippe eighteen months ago, followed by weakness, dyspnea on exertion, and cough which was never severe during the daytime. Expectorates daily about 100 c.c. of whitish sputum which is never blood tinged. Sleep greatly disturbed by cough and dyspnea. No fever, no nightsweats. After observation of three months by a competent physician in this city, the patient was declared not tuberculous. But while the sputum has always been negative bacter-

iologically, it has been found to give a positive albumin reaction. Physical examination shows signs of asthma, excepting some dullness over the left apex anteriorly and posteriorly. There are no signs of any active tubercular lesion.

Case III.—M. G., aged 40, tailor. Family and previous history negative. Was operated on one year ago for angioma cavernosa of the liver. While at the hospital he "contracted a cold" and began to cough and expectorate small amounts, blood tinged on one occasion, four months ago. No pain, no fever, no nightsweats; appetite and bowels in fair condition. Was told at the hospital where the operation was performed that his lungs were affected. In this institution he has been improving generally of late. The sputum on repeated examinations was negative bacteriologically, but chemically was found to give a distinct albumin reaction. Physical examination shows dullness over both apices, anteriorly and posteriorly. Bronchial breathing and crepitant râles over the left apex above and below the clavicle and the supraspinous space posteriorly. Along the left border of the sternum there is also harsh bronchial breathing, but there are no adventitious sounds.

Case IV.—Mrs. J., aged 62, seamstress. History that of a typical case of arthritis deformans. No cough, no expectoration, no fever, etc. Her only respiratory complaint is that she is greatly predisposed to "colds"—has had five attacks of bronchitis during the last two years. Sputum has been negative bacteriologically on repeated examinations, but positive as regards the albumin reaction. Physical examination reveals dullness over the left apex anteriorly and a few subcrepitant râles occasionally after cough over the left apex anteriorly and posteriorly.

In these four cases the albumin reaction of the sputum has drawn attention to the lungs and only the future course will show whether these cases are undoubtedly tuberculous. To be sure, many cases showing fewer physical signs, and without being positive bacteriologically, are considered tuberculous and even admitted to sanatoria. But we do not feel justified, for the time being, in deciding that these cases, admitted as they were for distinct diseases, which account for the greater part of their misery, are tuberculous. In a case in private practice which is not included in this series, the albumin reaction was of great service. Three months' observation has shown that the patient is tuberculous, while the physical signs did not warrant a positive diagnosis. It has been our experience that only active cases of tuberculosis give a decided albumin reaction; while quiescent or healed cases give only a faint reaction, often to an extent as to render the test doubtful. We have also found some cases of tuberculosis in which the test was negative at one examination and positive at another. These are mostly cases of fibroid phthisis with or without profuse expectoration. The following may serve as a type of the class of cases in which the albumin reaction is only faint:

Case V.—Mrs. A. K., aged 60. Family history negative. At the age of 21 she married a consumptive who died ten years later. She had four children, two of whom died in infancy, and one, a daughter, died at the age of twenty-five from pulmonary tuberculosis. She had pneumonia twenty-seven years ago and eighteen months later she began to cough, expectorate freely, and have repeated hemorrhages. She was admitted to Montefiore Home, where she remained for fourteen years; she was then transferred to Bedford Sanatorium, where she remained ten years, and now she has been transferred again to Montefiore Home. Physical examination shows dullness over both apices down to the third interspace, anteriorly and posteriorly, on the right side as low as the seventh and on the left as low as the fifth rib. There is bronchial breathing anteriorly and posteriorly corresponding to the areas of dullness, while the breath sounds at the left apex, immediately beneath the clavicle, have an amphoric quality. Over the lower lobes the breath sounds are diminished. Subcrepitant *râles* are heard all over the left side of the chest, and at the spot where the amphoric breathing is heard there are at times also found medium-sized and coarse mucous râles, especially on coughing. At one examination some sibilant and sonorous sounds were found all over the chest, especially over the left side. Her general appearance is rather good. On the whole we consider this a case of fibroid phthisis, running a slow chronic course with occasionaly exacerbations, when the amount of expectoration increases. Generally the quantity brought up is not large and shows no tubercle bacilli, and the albumin reaction is rather faint.

As already stated, we have met with cases of tuberclosis showing tubercle bacilli in the sputum, yet giving a negative albumin reaction. One of these was the case referred to above of cancer complicated by tuberculosis. The others are given here in detail:

Case VI.—M. K., musician, aged 32. Father died at seventy, probably of tuberculosis, otherwise family history is negative. Had typhoid at the age of twenty-five, and also pneumonia. Three years ago began to cough, expectorate, and lose weight and strength. A few months later he was told that he had consumption. He was admitted to Seton Hospital in June, 1910, and to Montefiore Home in August of the same year. Remained here till his death, which occurred July 26, 1911. A careful physical examination about a month before his death showed marked infiltration of the right lung, anteriorly to the sixth and posteriorly to the eighth rib, and also of the left lung down to the fourth interspace. These dull areas showed also bronchial breathing, and large moist râles, and some clics. Clinically there could be no question as to the diagnosis of pulmonary tuberculosis, which was confirmed by the fact that tubercle bacilli were found in the sputum on repeated occasions, and the very specimen examined on August 19, 1911, which gave a negative albumin reaction, revealed tubercle bacilli.

Case VII.—M. W., peddler, aged 53. Family history negative. His first wife died of tuberculosis twenty-seven years ago. He does not remember any diseases of childhood, but knows that he was a sickly child. Nine years ago, after an accident, he became very sick with cough, hemorrhage, chills and fever, losing weight and strength. On careful questioning it is elicited that he had been coughing for a number of years before, had nightsweats, had expectorated considerably, and was short of breath. Physical examination shows a barrel-shaped chest; dullness over both apices anteriorly down to the third rib on the right side and to the second on the left side, and posteriorly down to the seventh rib on the left and the fifth on the right side. There are sibilant and sonorous râles

all over the chest, suggestive of fibroid changes, while the breath sounds are rather feeble. Over the left apex anteriorly bronchial breathing and coarse moist râles are found, suggestive of an active process. There is also to be found a distinct friction sound at the lower part of the left axillary line. Repeated examination of the sputum in 1906 showed that tubercle bacilli were present, but since then several examinations have failed to reveal them. The albumin reaction is also negative.

It is thus evident that we cannot confirm entirely Roger's conclusion to the effect that every case of tuberculosis gives a positive albumin reaction. The three cases just detailed, showing tubercle bacilli in the sputum, and reacting negatively as regards the albumin test, militate against such a conclusion. The source of the albumin in pulmonary tuberculosis is probably the ulceration of the bronchi and pulmonary parenchyma. In advanced cases these ulcers are often healed by the formation of fibrous tissue, and in such cases the sputum secreted is of about the same character as that in simple catarrh of the respiratory tract. The fact that in some cases we found a negative albumin reaction at one examination, and a positive one at another examination, shows that during acute exacerbations, which these cases are known to pass frequently, the albumin may reappear owing to the breaking down of the protective fibrous wall.

The albumin reaction of the sputum, while not infallible, can be considered a valuable addition to our diagnostic aids. A positive albumin reaction in a case accompanied by expectoration is strongly suggestive of tuberculosis. If the patient is found not presenting signs and symptoms of emphysema with cardiac dilatation, the presumption in favor of tuberculosis is stronger. In the advanced stages of this disease a negative reaction does not always prove that we deal with a cured case, because we have met with cases showing tubercle bacilli, yet giving a negative albumin reaction. The test is very simple, any one can perform it as easily as the examination of urine for albumin, and it should, therefore, be applied in all doubtful cases. Very often it will shed some light on a case which may otherwise prove puzzling.

THREE CASES OF BRAIN ABSCESS.

By JACOB FRANK, M.D.,

CHICAGO, ILL.

SURGEON TO COLUMBUS AND GERMAN HOSPITALS, CONSULTING SURGEON TO MICHAEL REES AND COOK COUNTY HOSPITALS,

AND

G. B. HASSIN, M.D.,

CHICAGO, ILL.

HEAD-INSTRUCTOR IN NEUROLOGY, COLLEGE OF MEDICINE, UNIVERSITY OF ILLINOIS.

Brain abscess is always a fatal disease, unless properly diagnosed and timely treated. Spontaneous cure of this morbid condition, as reported in older literature,[1] is so rare that it cannot and should not be relied upon. Therefore, the treatment of brain abscess can be only surgical, provided the diagnosis is made early and correctly. The diagnosis has for its purpose, first, to define if there is in any given case a brain abscess, and if so, to determine in what portion of the brain the abscess is located. In other words, a focal diagnosis is of paramount importance in every case of cerebral abscess. In the following three cases we intend to emphasize the most salient diagnostic features of some forms of abscess of the brain.

Case I.—Mr. T. was seen by one of us (Hassin) about March 6, 1911, when he was complaining of severe headache, buzzing in the left ear, and deafness. The patient was about 45 years of age, of good habits, *i.e.* did not drink, did not smoke, and was leading a regular life in every other respect. At the time of the examination he looked very weak, yellowish-pale, and exhausted (cachectic). He preferred to lie in bed, complaining most of the time of headache, which was particularly severe in the left occipito-temporal region. His temperature was 98°; pulse, 78, full, of good tension. The appetite and sleep were poor; bowels, constipated. There was neither vomiting nor dizziness, but constant buzzing and ringing in the left ear. He comprehended everything, was answering questions rationally, but the answers were laconic. He was not drowsy, *i.e.* did not fall asleep during conversation, but appeared rather apathetic. He constantly talked of his headaches, but showed no speech disorders in the form of anarthria. When showed an object, for instance, a key, and asked to name it, he was unable to do so, but would explain its use and say that "it is a thing used for the door." When the key was put in his hands he would name it correctly. When asked a moment later again to name the same object, the key, he would show the same inability and give the same description of its use and recollect the right name when the key was in his hands. Calculations could not be performed. Thus 5 times 6 was 4, 7 plus 8 was 7. Besides the buzzing in the ears, the peculiar disorders of speech (the inability to name the shown objects right) the patient showed a remarkable depression of spirits. He would occasionally cry and groan, and moan from the severe headache, and repeatedly relate a history of an operation performed on him for ear trouble and claim that the ear operation "killed" him, "crippled" him, made him "hopelessly sick," and that there is no "help" for him. At the same time he showed a remarkable apprehension for his family, begging with tears in his eyes to be "helped" for their sake. Thus, the moral sphere was intact, while the intellectual sphere was considerably impaired (speech disorders and poor memory).

Two weeks previous to the examination he had a severe earache. A drum puncture was done, pus was evacuated, but there was no relief and the patient took to bed at once after the operation. Severe headache set in, accompanied by "fainting" spells, chills, and from this time on the patient started to talk of the operation and to suspect it as the cause of his troubles. Three months previously he had the grippe, but otherwise always was feeling good, never had a discharge from the ears, or any other ear lesion until two weeks previous to the examination for the present complaints. Ten years ago he was jarred by a horse and was on that account laid up in bed for several weeks. Aside from this accident and the grippe the patient always was in good health, intellectually and morally well developed. In two weeks, since the drum puncture, his vigor and health gave away, his countenance changed to that of a yellowish-pale one, mentioned above, with a greatly impaired intellect. There was complete adynamia: the weakness was so great that it was difficult for the patient to talk or sit up sufficiently long so that a more minute examination as for reading, writing, etc., could not be performed. The physical examination showed normal

heart and lungs, pain upon tapping of the occipito-temporal region, loss of bone conduction on the left side, and normal reflexes.

The diagnosis was that between traumatic neurosis and brain abscess. In favor of the former spoke the concentration of the patient's mind on his ear injury caused by the drum puncture, which could have produced a severe shock and thus result in traumatic neurosis. The depressed, melancholic condition was also in favor of the diagnosis of traumatic neurosis, but a closer examination disproved this, because buzzing and strange noises in the left ear, combined with deafness, headache, the previous history of an ear abscess and the peculiar speech disorders (optic asphasia), positively indicated a brain abscess.

I did not deem it advisable or necessary to wait for the results that a possible blood or lumbar puncture examination might have furnished, and I recommended immediate removal of the patient to a hospital for an operation. The facts obtained from the examination sufficiently warranted an operation, and further data that might have been furnished by blood or eye examination or lumbar puncture could have added nothing to the diagnosis. The operation was performed the next day by Dr. Jacob Frank in Columbus Hospital. A large abscess was found in the substance of the left temporal lobe. Unfortunately, the condition of the patient was so bad and the abscess so large that the results were unfavorable and the patient died five days after the operation. The interest of this case lies in the rôle the mental symptoms played in the diagnosis. The most prominent symptom was here the inability by the patient to name a common object when shown, but the ability to name it promptly when the shown object was taken or put in his hands. Such a phenomenon is called optic aphasia or, what is more correct, amnestic-optic aphasia. The latter is considered by Oppenheim the most characteristic, if not the pathognomonic, feature of an abscess of the temporal lobe, provided it is looked for. Indeed, the patient appeared perfectly rational, understood and answered questions, related his previous history, but, when examined more closely, showed deep intellectual defects. Besides the optic aphasia, another mental defect showed itself—in the form of poor memory. The patient would repeat the same story again and again and would forget what had been said to him a few seconds before. The poor memory was in this case as striking as the aphasia, and, what is still more remarkable, was present simultaneously with the latter. "Poor memory," says Oppenheim, "is mentioned in histories, but it seems that the aphasia was taken for memory disorders and as such was interpreted, especially in old casuistry, though even newer observers could not refrain from similar mistakes."[2] Our case disapproves Oppenheim's conclusions, as the facts speak for themselves.

The aphasia, poor memory and other intellectual disorders are liable to escape notice, notwithstanding their characteristic features, and the diagnosis is then rendered impossible. This is why the patient was refused admittance to a hospital where he was sent by an otologist and was turned away with the diagnosis of "neuralgia" and was instructed to come back a week later, when he was dead. If the above mentioned symptoms had been looked for by the hospital physician, such a blunder could have been easily avoided. This case can be considered a classis, a type of a temporal brain abscess, and was easy to diagnose. Unfortunately, not always are the symptoms so grouped as in this case, and the diagnosis, therefore, is sometimes extremely difficult to make. The following case can serve as an illustration.

Case II.—Mr. E. S., aged 40, consulted one of us (Frank) in Columbus Hospital for severe pain in the left leg which seemed to be sciatica. Having left the hospital he took the car for his place of business, a few miles away. Stepping off the car he got a sudden pain in the left ear and whole head. The pain was, according to the patient, "so severe that it took the feeling out of the whole head." He walked to the place of business with eyes closed. The pain gradually subsided and about 11 A. M., *i.e.* a couple of hours later, disappeared entirely, but returned the same night. The patient took to bed and started to complain of severe headache which caused him to groan and interrupted his sleep. The temperature was 102° in the morning, and at 6.45 P. M. it was 100°. The pulse was 70 and 82. On the next day he confused words and on the fifth day this confusion manifested itself in the form of peculiar speech disorders. Thus, pain in the limbs he called medicine; the nurse he called doctor; slippers, medicine; "You" was "I." He was very irritable and restless. When excited he would occasionally pronounce the word correctly, but immediately change it for "medicine." When asked how much was 4 times 5 he would say four medicines times seven medicines will make twenty-eight medicines. The ear examination, performed by an experienced aurist, proved negative; the blood count gave 11,700 white cells; and the Wassermann reaction was negative. A complete neurological examination was absolutely impossible to perform on account of the irrational condition of the patient. The only symptom that indicated a serious brain lesion was the paraphasia, which, in the absence of chronic and acute ear lesion, could not very well be explained. One could think of a serous meningitis, of a circumscribed encephalitis of the left temporal lobe, and then also of a brain abscess. The diagnosis could not be made with certainty and such a serious operation as removal of a brain abscess could not, therefore, be urged. The patient was left at home, was seen by a number of neurologists and surgeons, but the diagnosis could not be decided upon. At the same time the patient was getting gradually worse, became unconscious, and Dr. Jacob Frank decided to operate. An abscess of the temporal lobe was found discharging stinking greenish pus and containing streptococci. There was temporary improvement, but the condition was rapidly getting worse and five days after the operation the patient died. The post mortem showed an abscess of the temporal lobe of the brain that corresponded to the first two temporal convolutions and penetrated 2½ inches deep into the substance of the temporal lobe. The region of the large ganglia (lenticular nucleus, optic thalamus, and part of the caudate nucleus, and the Island of Reil) were destroyed.

Thus, in this remarkable case of a brain abscess, we did not have an optic aphasia, as in the preceding case, but rather a paraphasia. Then we did not have the etiological factor, the acute purulent otitis as in the previous case, and the diagnosis, therefore, could not be made early enough and with certainty. Oppenheim positively states that the diagnosis of brain abscess cannot and should not be made if there is absent or unknown the pri-

mary source of suppuration, as lesion of the ear, nose, throat, etc. The most careful search for a suppuration or other ear lesion in this case, done by a very competent aurist, did not reveal any ear trouble. It is true that the patient complained of a severe earache at the time he took to bed, but then it was so acute, so sudden, and transitory that it is hard to comprehend how an abscess of so large a size could form in such a short time. We must admit that the streptococci found in the pus of the abscess were the cause of the inflammation that originated probably first in the middle ear and then penetrated into the brain. It is certainly to be regretted that only a removal and dissection of the brain could be obtained and that a minute investigation of all parts of the ear were omitted. If we assume that the cause of the temporal abscess in this case was an acute ear lesion, *i.e.* the abscess was of otitic origin, which undoubtedly was the case in the previous patient, then we have two cases of brain abscess in which the cause was an acute otitis. This is rather unusual if we take into consideration the statistics of authorities that in 90 or 91 per cent. of brain abscesses the cause is a chronic otitis, while only in 9 per cent. is the cause an acute otitis. The most careful and repeated interrogation of the patient's relatives, highly intelligent people, failed to reveal any probable or possible source of the abscess. There was absolutely nothing in the previous history, as trauma, infection, etc., that could help in diagnosing the case, and thus we had one certain symptom, the paraphasia, without the other factor that is of very great importance, the knowledge of the primary source of the infection. In 10 per cent. of cases there could be found no etiology (Oppenheim) and Martius thinks it possible for an abscess to form in the brain through direct invasion of microbes of influenza, epidemic cerebrospinal meningitis, pneumococci, etc. Oppenheim accepts this view of Martius, who calls such abscesses, that are not due to a primary focus somewhere else in the body, primary. Probably we had to deal in this case with a primary abscess of the temporal lobe of the brain caused by a streptococcus infection. If we disregard the primary source of brain abscess which sometimes cannot be found, we then must rely on other symptoms of which none is so constant, for the temporal brain abscesses, as the aphasia or paraphasia. The speech disorders are of tremendous significance and, as our second case shows, are alone sufficient to lead to the correct diagnosis and to immediate surgical interference. There is another difference in these two cases, namely, the temperature. In the first case the temperature was before the operation normal, while in the second it was elevated. Some cases of brain abscess run with a normal or subnormal temperature which, according to Macewen,[3] happens especially in uncomplicated cases.

Case III.—In this case we had to deal with a girl 21 years of age. Eight years ago, while crossing the ocean, she was seized with a severe pain in the right ear. The pain was unbearable, lasted two days, and then disappeared. There was neither headache, nor vomiting, onr fever, but she could not sleep for two nights from the earache. There was no discharge from the ear afterwards, she did not have any dizziness or troubles with the eyes, but complained of poor hearing on the right side. For six years she was feeling fine and forgot all about it. Two years ago the earache returned and she was relieved by a drum puncture. She knows that blood showed, but no pus. As there was no relief from the earache she had six weeks later another puncture done, and this second operation was soon followed by headache. The latter was confined to the parietal region, was accompanied by vomiting, buzzing in the left ear, and dizziness. She took to bed, could not sleep, and suffered immensely from headache and buzzing in the ear. The suffering kept on for three days and then one of us (Frank) was consulted. She was immediately sent to Columbus Hospital, where she vomited and became unconscious. The examination showed that the mouth was drawn to the left side, the right eye was widely open, there was paresis of the right arm and right lower limb, she could not hold anything in the right hand, and the right foot was helpless. The operation was performed the next morning by Dr. Jacob Frank, who found a large abscess in the right region of the cerebellum. The patient was unconscious for about two weeks following the operation and on the third week improvement set in, which, in five weeks, was followed by complete recovery. At the present time, two years since the operation, she is feeling perfectly well, is working in an office, but has a discharge from the right ear and shows a paresis of the right facial nerve. She also shows a marked horizontal nystagmus, which is common in cerebellar abscesses but very rare in temporal ones. A noteworthy feature in this case was the presence of a homolateral paralysis of the right half of the body, which again is very peculiar for cerebellar and which does not occur in temporal abscesses of the brain. Macewen explains the paralytic phenomena by pressure of the abscess upon the pyramidal tract. The paralysis will be crossed if the pressure takes place above the crossing of the pyramidal fibers, and homolateral when it occurs below, which was evidently the case in our patient. The presence of paralysis, combined with vertigo, headache, and nystagmus, is as characteristic for cerebellar abscesses as aphasic disorders for temporal ones.

It is difficult to form any conclusion from these three cases in regard to prognosis that surgical treatment of brain abscess gives. The statistics give a better prognosis for temporal abscesses than for those of the cerebellum. The average percentage of recovery is 72 for the former and 45 for the latter. Macewen was even more successful, in fact, the most fortunate and succesful of all that operated for brain abscess. Of 19 cases he obtained excellent results in 18, and among them were most dangerous and desperate cases of brain abscess. Oppenheim and Cassirer think that the percentage of cure given by the statistics is too high, because only favorable cases were, in their opinion, reported, and because the results were too soon published. In our cases the results were rather discouraging, but this was also the case in the hands of the most experienced surgeons, and should not deter us from further attempts in the same direction, as the third case of our series, as well as numerous cases reported in literature, proves beyond doubt that an operation in cerebral abscess may be a life-saving procedure.

METHYLENE BLUE TEST IN URINE OF CANCER PATIENTS.

By J. RUSSELL VERBRYCKE, Jr.,

WASHINGTON, D. C.

Any test which will enable us to diagnose carcinoma earlier or which will aid us in the diagnosis will be most welcome. So far no pathognomonic reaction has been discovered, but several more or less valuable means of contributory evidence have been described.

With the purpose of endeavoring to find the real value, if any, of the disappearance of the methylene blue coloration after addition of the dye to the urine of cancer patients, as described by Fuhs and Lintz in the *Journal of the American Medical Association*, June 24, 1911, I have performed the test a number of times. The patients tested have been sufferers from digestive disturbances and I wished particularly to note the frequency of occurrence of a positive reaction in these cases and to ascertain whether we could be helped in determining whether or not malignancy had developed in certain chronic ulcers. I had intended performing the test on one or two hundred non-cancerous patients and the number of malignant cases seen during that time before giving results, but after examinations in 50 cases certainly not malignant, 4 cases of gastric carcinoma and one probable cancer, I have reached such positive conclusions as to render it to my mind a waste of time to continue. The results will be found in the accompanying table.

Diagnosis	Number Examined	Positive	Partially Positive	Negative
Cancer	4	1	2	1
Cancer suspect	1	.	.	1
Spastic constipation	2	.	2	.
Enteroptosis and colitis	2	1	.	1
Hyperacidity and arteriosclerosis	1	.	.	1
Constipation, nervous dyspepsia	3	1	1	1
Colitis	10	3	2	5
Hyperacidity	3	.	.	3
Hyperacidity, intestinal toxemia	3	1	.	2
Enteroptosis, atony	3	1	.	2
Achylia	3	1	1	1
Normal	2	.	1	1
Neurasthenia	4	.	2	2
Intestinal indigestion, chronic nephritis	1	1	.	.
Intestinal toxemia	1	1	.	.
Atonic constipation	2	1	.	1
Hemorrhoids	1	.	.	1
Indicanuria, gallstone suspect	1	1	.	.
Subnutrition	1	.	.	1
Enteroptosis	6	2	2	2
Chronic gastromesenteric ileus	1	.	.	1
	55	15	13	27

I at first thought that though a positive test was not an unvarying indication of malignancy, still that a negative result would have considerable value, but I have been forced to even abandon that hope in view of the fact that three patients with cancer of the stomach, proven at operation, gave negative findings. One was a case of gallstones and chronic gastric ulcer, with well-marked cancerous degeneration and glandular involvement. The patient's urine showed absolutely no change whatever 24 hours after addition of the methylene blue. Patient No. 3 was found to have a widespread scirrhus cancer of the stomach, and yet gave a very incomplete reaction, much less than that obtained in many non-malignant patients. After 24 hours the lower third of the urine was practically completely decolorized, but the rest was from light green at the middle third to blue at the top. Another patient was found at operation to have tremendous inoperable carcinoma of the stomach, and yet the test in this patient also failed. Still a fourth, who has not yet been operated upon has a mass in the gall-bladder region with a hard stony feel of malignancy. If her consent can be obtained to operation she also will probably be found to have cancer, and yet she gives a negative reaction. From the number of positive results in certain nonmalignant cases it is evident that the test cannot even be credited with giving contributory evidence when positive. Again, if the test is of any value it should certainly in cases like the above give positive results. Hence not even a negative reaction is of any worth, and we must still look to the future for more certain laboratory aids to the diagnosis of cancer.

The cause of the reaction I am unable to explain. I have proven that it has nothing to do with acidity or alkalinity, but that it must be due to a definite chemical change induced by the excretion in the urine of either a chemical substance or an enzyme. I should say that it was most likely the latter, since I have found that boiling the urine before adding the methylene blue prevents the decoloration. But, on the other hand, the addition of a few drops of a urine which reacted positively to a test-tube full of a negative urine did not result in decoloration. It would be interesting to know just why some urines do have the property of decolorizing methylene blue while others do not, but it would seem that the test is useless for purposes of diagnosis.

I wish to express my indebtedness to Dr. Wm. Earl Clark for the privilege of making examinations on a number of his patients.

2307 First Street.

Sigmoiditis and Infection of the Internal Genital Organs in the Woman.—Jean Poulain says that the position of the sigmoid free in the small pelvis held in position by its mesentery and coming in contact with the female genital organs allows of the propagation of inflammation from one of these organs to the other. This infection is propagated not by the blood-vessels or lymphatics, but by means of the adhesions produced in the peritoneum. These may be many and close enough to cause a paraintestinal tumor as a point of departure for obstruction. The infections of the sigmoid are primarily caused by constipation and are communicated to the genital organs. If treated early they may be cured, while if left alone they cause irreparable lesions of the genital organs. The germs that cause inflammation to pass from the sigmoid to the adnexa are the colon bacillus primarily, the streptococcus, typhoid bacillus, and ameba of dysentery. The one that most frequently passes from the adnexa is the gonococcus. Besides these are streptococci, staphylococi, and tubercle bacilli. We get suppurative and plastic inflammations, the latter producing adhesions that bind down all of the organs contained in the pelvis. In these cases we should try a long course of irrigations of the intestine with hot water and salt, before we undertake operation.—*Journal des Sciences Médicales de Lille.*

Contribution to the Study of the Ovarian Function by Unilateral Castration.—Francesco Valtorta has attempted to ascertain whether after unilateral castration the remaining ovary will take up successfully the entire ovarian function. To this end he castrated rabbits unilaterally and killed them after various intervals, examining the ovaries histologically. He found that there was a uniform increase in size of the remaining ovary, which was due to an increase in the number of Graafian follicles, with slight increase in the stroma and no evidences of changes in the vessels indicating sclerosis. Hence the author finds that the ovarion function is supplied by increase in size and function of the remaining ovary.—*Annali di Ostetricia et Ginecologia.*

MALARIA AND MATHEMATICS.

ABOUT ten years ago Ferdinand Hueppe prophesied that the time would come when the methods of mathematics would be applied to the study of disease. Each morbid entity would have its own algebraic equation, whose terms would represent the different etiological factors. The variability of the latter would in no way disturb the constancy of the relationship expressed by the equation. The algebraic formula may be conceived as corresponding to a definite curve, every point of which bears a constant relationship to every other point on the curve. Biometricians have long since appropriated the methods of the calculus in the interpretation of the phenomena of life. The Mendelian doctrine of heredity is the fruit of the application of simple mathematical principles to certain well-known manifestations of inheritance. The charted curves of the statisticians, the life-tables of the actuaries, the calculations of sanitarians all testify to the important rôle of mathematics in the advancement of biological science. That the apparently elusive phenomena of pathology might lend themselves not merely to simple methods of enumeration, but also to expression in the form of unvarying mathematical equations, requires solely that the etiological factors should be definitely known. The variability of these factors would in no way affect the constancy of the equation. In other words, using the language of analytical geometry, disease, in its multitude of forms, is in each instance a function of a number of variables, such as heredity, climate, soil, meteorological conditions, nutrition, intoxication, microbic invasion, etc. As soon as these factors are established in the case of any particular morbid condition, the knowledge of the laws that govern the existence of this condition is elevated to the ranks of an exact science.

Medicine of to-day is remote from being an exact science, but it is slowly moving toward this goal. It is greedily appropriating as its own the conquests in physics, chemistry, and mechanics, and is fully armed with the experimental methods that have placed the latter upon a high plane. The subjugation of disease which future generations will behold will be the outcome of a scientific warfare, in which every plan of battle will be carefully drawn and in which the strength of the enemy will be accurately known. Trained sanitarians will constitute the engineering corps of this conquering army. Does medical science as yet furnish any example of the reduction of disease to the rule of thumb? In answering this question one has but to point to the eradication of yellow fever from Cuba and the Canal Zone, and the control of malaria in many parts of the world. The latter disease, in particular, is one whose cause and manner of propagation are definitely known, together with the laws that govern its prevalence and diffusion.

Ronald Ross has made important researches into the epidemiology of malaria and into the circumstances that govern its diffusion, and has demonstrated mathematically that the laws underlying the prevalence of malaria in any community may be accurately determined. In his book entitled "The Prevention of Malaria," recently reviewed in these columns, Ross discusses the laws which regulate the amount of malaria in a locality and shows how the prevalence of this disease may be measured with mathematical precision. It is impossible in this place to discuss even briefly the various and somewhat intricate steps in the mathematical reasoning that enables Ross to formulate his remarkable conclusions. It may suffice to point out certain striking aspects of this form of deduction in order that the significance of these conclusions may be firmly grasped.

In discussing the conditions required for the production of new infections in a locality, Ross lays down the important principle that few or no new infections will occur unless the persons with gametids (sexual forms) in their blood and the carrying anophelines are sufficiently numerous. It is stated that this proposition is the basis of the public prevention of malaria. As the result of his calculations, Ross shows that the ultimate malaria-ratio (the proportion of malarious to healthy individuals) will vanish if the number of different anophelines to each person is less than about 40 per month. The amount of malaria in a locality tends toward a fixed limit determined by the number of malaria-bearing mosquitos and by other factors. There are numerous laws that regulate the number of anophelines in a locality. The output of mosquitos from marshes may vary within wide limits. The average life of the winged insects must be taken into account. Only about one-third of the carrying anophelines live for ten days—long enough to allow the plasmodia to mature in them. The proportion of mosquitos which succeed in biting human beings is also an important factor: Thus, a quarter of the anophelines may succeed in biting human beings once, a third may live for ten days more, and a quarter may succeed in biting again—that is, only about 1-24 of the females can ever have any chance of carrying malaria. Other factors that must be considered are the number of anophelines in a unit of area and the number in houses; the variation in mosquito-density from place to place (mosquitos tend to diminish with distance from their breeding place); the variation of mosquito-density from time to time; the variation of mosquito-density due to food (mosquitos tend to swarm in crowded and poor habitations); the mosquito-output varies with the extent of breeding surface; there occur flock migrations of mosquitos.

their visitation of and transportation by ships and vehicles; they are transported by rivers and winds, and are also subject to random scatter from a given point. The enumeration of these factors illustrates the extreme complexity of the task of determining the laws governing the prevalence of anophelines in any given locality.

Those who in their college days reveled in the glories of the higher mathematics will have no difficulty in following the formulæ that Ross presents in an imposing array. Of these there stand out two important equations. The first of these is termed the "variation formula" and indicates the manner in which malaria varies in a locality. The formula is as follows:

$$m_1 = m + b^2\ s\ i\ a\ (1—m)\ m—r\ m$$
$$= m + 0.005\ a\ (1—m)\ m—0.2\ m\ \text{(say)}$$

In this equation m is the proportion of infected persons at the beginning of the inquiry; a the proportion of anophelines to each person; r the rate of recovery; b the proportion of anophelines which succeed in biting men; s the proportion of anophelines which succeed in maturing the parasites; i the proportion of patients with gametids in their blood; and m_1 the proportion of infected persons at the end of the period of inquiry. The second formula is named the "static formula" and represents the final or static level M, to which the portion of infected persons falls so long as the proportion of anophelines and the other factors remain about constant. The static formula is as follows:

$$M = 1—r\ /\ b^2\ s\ i\ a$$
$$= 1—200\ r\ /\ a\ \text{(say)}$$

The exact numerical values of b, s, i do not affect the validity of the above equations.

The connection of malaria with marshes is shown by the fact that in the static formula the larger a becomes the more M approaches to unity—that is, the whole population becomes infected. An impermeable soil, with its greater collections of surface water, tends to increase a, the number of anophelines. Abrupt hillsides have little malaria as a rule, while flat plains at the foot of mountains are markedly unhealthy. Increased rainfall not only increases the mosquito output, but also increases relapses, increases the biting factor b, and reduces the recovery factor r. Winter rain may reduce r, but it has but little other effect; much spring rain fills the pools and favors the breeding of mosquitos; malaria inoculation, however, occurs most frequently at the beginning and the end of great summer rains. Increased temperature causes increase of all factors except r, the recovery factory, which tends to decrease. As regards altitude, malaria tends to diminish and cease at an altitude of about 1,600 to 4,900 feet above the sea-level. Malaria abounds less in the center of towns and more in the suburbs. Other things being equal, the malaria ratio is higher among a scattered rural population than in a dense urban one.

Space will not permit the discussion of other important factors that influence the malaria ratio, factors such as region, species of anophelines, the social condition of the people, the possible effect of malaria on the anophelines, seasonal variation, the effect of imported cases, the effect of mass-migrations, slow changes in endemicity, etc. This bare outline may suffice to indicate the extraordinary possibilities which this method of mathematical analysis promises in the elucidation of the manifold problems of disease.

THE ECONOMY AND THE FOOD VALUE OF CHEESE.

In a report by C. F. Doane on "The Digestibility of Cheese"* several varieties, but especially the American or Cheddar cheese, and some European cheeses, are considered under a great diversity of conditions; in the experiments submitted the dairy division of the Department of Agriculture had the cooperation of its office of experiment stations. The common American or Cheddar cheese (the so-called "full cream" of the dealers) is foremost in the quantity made and consumed. Emmental, the so-called Swiss cheese, is perhaps second, while from an economic viewpoint the kinds of cheeses made from skimmed milk, principally cottage cheese, are of great importance. By reason of their condimental value and their high flavor, Camembert and Roquefort might seem entitled to special consideration, but they are expensive and of such a nature that few would care to eat more than a small quantity at a time.

Some heretofore perplexing questions would seem to have been settled in this report. The comparative digestibility of green and cured cheese has been debated, for example. The Cheddar was formerly eaten when it had gone through the "ripening" or "breaking-down" process, in which some evident but not perfectly understood chemical and physical changes take place; there is in this process a gradual change from a rubbery or elastic to a mellow and partially soluble consistency with, *pari passu*, a decided development of flavor. Another debatable belief has been that cheese in any stage of ripening causes constipation. Now, there is a marked difference in the physical characteristics of the green and cured products. The water-soluble material in well-cured cheese is high, whilst in the uncured product it amounts to almost nothing. It is very likely that these evident physical and chemical differences have been largly responsible for the popular misconceptions. The milk solids are very digestible and make an almost perfect food. With the addition of rennet and the development of lactic acid some chemical changes take place; but why should these transform digestible solids in milk into indigestible solids in cheese? Again, why should cheese of any sort, green or otherwise, tend to constipation? This almost universal belief among cheese-makers is probably due to the fact that many people are so fond of the mild-flavored curd as to eat much of it when it is constantly at hand; and the digestive disturbances attributed to peculiarities in the cheese itself are no doubt due merely to overeating.

As to the actual food value of cheese, "people who are sometimes considered as authorities on dietary subjects" are of opinion that cheese is not a

*Doane, C. F., Circular 166, U. S. Department of Agriculture.

staple food product, being valuable only as a luxury or as an appetizer. Yet cheese is an important, indeed an essential, part of the dietary of most European peoples; and, as compared with other highly nitrogenous foods, it is decidedly economical—an important consideration for poor and hard-working folk. Skim-milk cheese should especially engage the attention of the laboring classes. When this cheese is sold for a whole-milk product it is a fraud that is a positive injury to the dairy business; but cheese made from skim-milk and sold as such is worthy of serious consideration by both producer and consumer. No doubt much of this cheese will be a product profitable to the dairyman and a good cheap food. Cottage cheese is another inexpensive and palatable product.

The quantity used in these United States is almost negligible by comparison with some other products of less food value and of inferior palatability. Most of the cheese we do eat is unprepared, while on the Continent it is sprinkled on other food—as vegetables—or cooked with the food. Many European varieties are made exclusively for use in cooking. The Parmesan is a hard cheese made from skim-milk; the sap sago cheese is made from skimmed milk and is highly seasoned with herbs. The Italians have cheese grated and they use it for flavoring as we use salt and pepper; their macaroni with cheese is a famous and very nutritious dish. And what excels the cheese omelet in flavor and nutritious qualities? "People who like a highly-flavored cheese never become tired of it."

Comparing the food value of cheese with that of other highly nitrogenous foods, only dried beef among all meats carries as high a protein percentage; and as dried beef contains a much greater percentage of water, the other food constituents, aside from the protein, are much less than is found in cheese. Fresh beef has, weight for weight, little more than half the food value of cheese in either protein or fat; and the same is true of practically all other fresh meats, which have oftentimes so large a refuse percentage and invariably so large a water percentage that they are notably inferior to cheese in food value. Bacon and fat pork are exceptions, but their food value is mostly in the fat, which can be and is in large measure replaced by the vegetable carbohydrates at a much less cost with greater digestibility. Fish and pork have each a notably large percentage of refuse, while eggs have a high percentage of water. In point of economy cheese compares very favorably indeed with these other foods; practically the only product that rivals cheese in food value and cheapness is dried beans. Our people, especially those who need to be economical in food buying, would indeed do well to attend somewhat to cheese.

SYPHILITIC EYE AFFECTIONS WITHOUT HISTORY OF SYPHILIS.

The recently introduced biological tests are revealing the intimate nature of many affections of obscure etiology, just as the original tuberculin reaction shed light on the character of diseases now known to be either tuberculous or paratuberculous. This is true of the Wassermann reaction for syphilis, especially in reference to ocular diseases, certain of which must be regarded as either syphilitic, metasyphilitic, or occurring by preference in syphilitic persons.

At a meeting of the Berlin Ophthalmological Society last July Glantz reported some statistics of the Wassermann reaction in individuals with ocular affections of nonsyphilitic character and without syphilitic history. Of 239 such cases, 39 gave positive findings. In the tabulated material Glantz does not discriminate between positive reactions, so that we are left to infer the nature of the malady from the relative frequency of positive and negative findings. Thus in diffuse parenchymatous keratitis, an affection practically of syphilitic origin, nearly all the cases reacted positively. The cases with negative results may have been under specific treatment. On the other hand in focal sclerokeratitis, presumably nonsyphilitic, there was a positive reaction in a very small number of cases. This was also true of episcleritis and iridocyclitis. In certain affections considered broadly as entities there was a large contingent of both positive and negative finds, the former predominating. Here belong iritis, scleritis, non-tabetic ocular palsies, affections of the choroid with vascular implication, and optic neuritis.

Virtually positive were the tabetic eye affections, diffuse parenchymatous keratitis, retinitis proliferans, affections of the choroid without vascular implication, and primary retinitis pigmentosa. On the other hand inflammatory affections of the choroid and of the retina in the form of a focus in the macula with persistent scar always gave a negative reaction.

The Climate of California.

In the *Southern California Practitioner* for September, 1911, is an article by Mr. W. J. Ballard, a resident of Los Angeles, eulogizing California generally and Southern California in particular as a desirable country in which to live. From the description it would appear that Southern California is an ideal place of residence for those who require a warm, dry, and equable climate. According to Hilgard, California corresponds in its climatic features to the Mediterranean region of Europe and Africa—a grand Riviera with a partial background of the desert as well, where the date palm and the ostrich find a congenial home and alluvial plains are found equaling in richness the famed delta of the Nile. Allowing for the natural prejudices in favor of the climate of Southern California by an inhabitant, there is little doubt that this region is highly blessed as regards atmospheric conditions. It is particularly, perhaps, to be recommended for those whose nervous system is out of gear and who need an equable, restful temperature.

Artificial Respiration by Mechanical Devices.

According to Roth (*Berliner klinische Wochenschrift*, September 18) an apparatus has for some years been available in Germany and elsewhere, designed to supplant the ordinary manual method of securing artificial respiration. The author has tested it on animals and on the human cadaver, and says that it is ingenious, technically perfect, and works automatically. Oxygen is insufflated into the trachea and lungs and the air contents of

the latter are then aspirated, the resulting thoracic movements of the cadaver being startling in appearance. The oxygen is generated in a bomb and passes through a tube, which is connected with an air-tight mask fitted about the nose and mouth, the tongue having first been drawn strongly forward. Oxygen is prevented from entering the stomach by gentle pressure on the esophagus. The apparatus is portable and may be operated by one person. It has seemingly never been tried on the living subject, so that its utility is as yet merely theoretical.

Treatment of the Dysphagia in Laryngeal Tuberculosis.

Few conditions are more distressing than the dysphagia which nearly always accompanies tubercle of the larynx. The patient is usually able to be about, for the pulmonary lesions need not be far advanced. He often craves solid food and that is what he most needs; yet he is obliged to subsist on liquids. The ordinary method for securing some respite with the possibility of a relative cure consists in cauterizing the ulcers. In many cases, however, relief obtained is of very brief duration. Bearing in mind the great advances along the line of local anesthesia, including anesthetization in the continuity of nerve trunks, the thought asserts itself that some such procedure might be of use in laryngeal tuberculosis; and further recalling the utility of deep alcohol injections in neuralgia, one is moved to test the latter in the same affection. Bouvier, at a local medical meeting held at Giessen last May, reported eight cases in which he anesthetized the internal ramus of the superior laryngeal nerve by a deep injection of alcohol. In only one case was the result negative, but here a second injection two days later secured six weeks of analgesia. In the others the latter promptly appeared—once in two hours, and generally in from ten to twenty-four hours. The average duration of the analgesia was four to six weeks, minimum three weeks. From 1½ to 2 c.c. of 85 per cent. alcohol was injected at a temperature of 45° C. The injections were painful for the time being and in half the cases otalgia was set up. The subsequent relief from suffering and the moral effect on the patient were, however, most striking. It is, of course, not claimed that the lesions themselves are benefited, and the assertion of some writers that abolition of pain is in itself a local therapeutic agent probably cannot hold good in these cases.

News of the Week.

St. Luke's Hospital.—A new pavilion to be used as the Outpatient Department of St. Luke's Hospital, New York, was opened on October 19, St. Luke's Day. The building was provided for by a bequest of $250,000 from the late Mrs. John G. Heckscher, given in memory of her parents, William L. and Maria L. Travers. It fills out the northeast corner of the quadrangular plan on which the hospital is constructed, and will be known as the Travers pavilion. The lower two floors will be used for the dispensary, and the upper two have arrangements for treating patients in the open air. The other floors will be used as dormitories. At the annual meeting of the Board of Managers held after the dedication exercises it was announced that during the year ending September 30, 1911, treatment had been given in the hospital to 17,531 patients, the total number of days of treatment being 110,000. During the same time legacies to the amount of $19,000 were received. Now one of the best equipped and handsomest hospitals in the city, it is interesting to recall that St. Luke's was started with the gift of one dollar made by a sick girl to her rector, the Rev. Dr. Muhlenberg of the Church of the Holy Communion, with the request that it be used to help build a hospital. At the next Sunday service the clergyman showed this money to his congregation and declared that it should found a hospital to be known as St. Luke's The one dollar foundation has grown to several millions.

The New Medical Directory.—The Medical Directory of New York, New Jersey, and Connecticut for the year 1911 has just been issued. The total number of physicians in the three State lists is 17,624, of which 13,641 are in New York State, 2,582 in New Jersey, and 1,401 in Connecticut. Of the 13,641 in New York State, 5,093 are resident in Manhattan and the Bronx, 1,884 in Brooklyn, 205 in Queens, and 67 in Richmond, making a total of 7,249 in New York City.

New York County Medical Society Nominations.—At a meeting of the Medical Society of the County of New York, held on Monday of this week, the following nominations were made: *President,* Dr. Charles Gilmore Kerley; *First Vice-President,* Dr. Brooks H. Mills; *Second Vice-President,* Dr. T. Passmore Bevens; *Secretary,* Dr. John Van Doren Young; *Assistant Secretary,* Dr. J. Milton Mabbott; *Treasurer,* Dr. Charles H. Richardson.

Diphtheria in Indianapolis.—It is reported that diphtheria prevails almost to epidemic extent in Indianapolis. Moving picture shows and similar places of amusement have been counseled not to admit children, and parents have been requested by the health authorities to keep at home all children under 16 years of age.

Two Inebriate Hospitals for New York.—The Inebriety Board is about to build a hospital on Kingston avenue, Brooklyn, on land given to it by the Department of Charities, and another on Blackwell's Island, for the reception of confirmed inebriates in accordance with the new law.

Notification of Industrial Diseases.—A circular has been sent to physicians in this State, calling attention to Chapter 258 of the Laws of 1911 which requires medical practitioners in New York State to give notice to the Commissioner of Labor of every case attended by them of poisoning by lead, phosphorus, arsenic, or mercury and of every case of anthrax or of compressed air illness, if such disease was contracted as a result of the nature of the patient's employment. Failure to give such notice renders a practitioner liable to a fine not exceeding ten dollars. By the specific terms of the law immediate notification of each case coming to the practitioner's attention is required, and the notice must state the name of the patient, his postal address, his place of employment, and the disease from which he is suffering. It is also required by the Commissioner of Labor, in accordance with the law, that the patient's occupation or trade shall be specified. Blank forms for such notification will be supplied by the Bureau on application. Notices must be mailed to the Bureau of Labor Statistics, Capitol, Albany, N. Y. As usual, no provision is made for compensating the physician for the time and labor consumed in procuring and filling out these blanks or even for reimbursing him for the amount paid out in postage.

The Nobel Prize.—Prof. Allvar Gullstrand of the University of Upsala, Sweden, has been awarded the Nobel Prize in medicine for 1911, for his research work in dioptics in connection with his study of the eye.

Monument to Servetus.—A statue of Michel Servetus, the Spanish physician and controversialist, who may have been the discoverer of the circulation of the blood, antedating Harvey by a hundred years, and who was burned at the stake for heresy, was unveiled at Vienne, France, on October 15. This is the third monument erected to Servetus in France. There is also one in Geneva where he suffered martyrdom. Prof. Richet of the Paris Faculty of Medicine paid homage to Servetus as a great physician, and many notables representing the religious world were also present.

Aviation Victims.—With the death of Ely on October 19, the list of persons killed in aeroplane accidents has reached 101, of whom seventeen were Americans. The first person to be killed through an accident to an aeroplane was Lieut. Selfridge, who died in 1908, the only victim that year; but in 1909 there were 4, in 1910, 32, and so far in 1911, 64 deaths. Only one woman, a Frenchwoman, is included in the list.

Quarantine Against Colon.—The ports of Jamaica have been quarantined against vessels from Colon, because of the report of a case of plague at the Ancon Hospital in the Canal Zone.

Surgeons of North America.—The second annual session of the Clinical Congress of Surgeons of North America will be held in Philadelphia on November 7 to 16, 1911, under the presidency of Dr. Albert J. Ochsner. The program includes clinics held by the leading surgeons of Philadelphia each day, and seven evening literary meetings, at which physicians from all over the country will present and discuss papers. Full information can be obtained from the General Secretary of the Congress, Dr. Franklin H. Martin, 1210 Columbus Memorial Building, Chicago.

International Eugenics Congress.—The Eugenics Education Society has arranged for an International Congress to be held in London from July 24 to 30, 1912, under the presidency of Major Leonard Darwin. The papers will be grouped in four sections: The Bearing upon Eugenics of (1) Biological Research, (2) Sociological and Historical Research, (3) Legislation and Social Customs; and (4) Consideration of the Practical Applications of Eugenic Principles.

Harvey Society Lectures.—The Harvey Society announces the following completed list of lectures for 1911-12: *October* 28, "Narcosis," by Professor Max Verworn; *November* 11, "On Freud's Psychoanalysis," by Dr. J. J. Putnam of Harvard University (provisional); *November* 25, "Illuminating Gas and the Public Health," by Professor W. T. Sedgwick of the Massachusetts Institute of Technology; *December* 16, "A Consideration of the Nature of Hunger," by Professor Walter B. Cannon of Harvard University; *January* 20, "Unit Characters in Heredity as They Appear to a Paleontologist," by Professor Henry Fairfield Osborn of Columbia University; *February* 3, "The Relations of Modern Chemistry to Medicine," by Professor T. W. Richards of Harvard University; *February* 17, "Current Views Regarding the Nutrition of Man," by Professor R. H. Chittenden of Yale University; *March* 3, "Old Age, Death, and the Meaning of Conjugation in Lower Animals," by Professor H. S. Jennings of Johns Hopkins University; *March* 24, "Malaria," by Dr. W. S. Thayer of Johns Hopkins University. As previously announced the lectures are given on Saturday evenings at 8.30, at the New York Academy of Medicine, and are open to the public.

Children and Street Accidents.—The principals of the New York City public schools have been requested to instruct their pupils in the dangers of "tagging" onto street cars, wagons, and other vehicles, in the proper way of getting on and off of street cars, and in the safest way of crossing a street. It is pointed out that during the twenty-one months prior to last September there were 46 children killed by automobiles and 140 injured; 29 killed by trolley cars, and 17 injured; and 164 killed by wagons and 23 injured.

Dole for the Blind.—The annual distribution of New York City appropriation for its blind was made recently, when 544 persons received a gratuity of $50 each. All the beneficiaries were adults and dependents.

Value of Blood.—Alleging that three pints of his blood are worth $5,000, a young grocery clerk of Perkinsville, Ind., has brought suit for this amount against a wealthy farmer, who benefited by a transfusion of the blood. The recipient considered $40 ample payment. Hence, the suit.

Tuberculosis in Workhouse.—The exposé by Mr. Upton Sinclair of conditions at the New Castle County workhouse, Delaware, especially in regard to the prevalence of tuberculosis among the inmates, resulted in the appointment of a board of physicians to examine into the conditions, and this board has sustained the charges in many respects, recommending the establishment of an exercise yard and greater control of the negro prisoners. Seven negroes in the institution were found to be hopelessly ill.

Verdict Against a Hospital Reversed.—A verdict of $30,500, received by a bicyclist, who was run down and injured by a St. John's Hospital, Brooklyn, ambulance, has been set aside by the Court of Appeals of New York, which finds that the driver of the ambulance was the servant of the keeper of the livery stable, and not of the hospital, and that the hospital therefore was not liable in spite of the fact that a hospital surgeon was in the ambulance at the time, since the latter was not shown to have participated in the driver's negligence.

Child Hygiene.—The Board of Estimate of New York City has under consideration a plan for extending the work of child hygiene by providing city-paid dentists and oculists to treat children in the public schools. Of the children examined in 1910, 11.2 per cent. were found to have defective vision, and the need for dental treatment has been overwhelmingly demonstrated. Medical inspection, which is now carried on only in the public schools, will probably be extended to the parochial schools, and provision will be made for a systematic re-examination of children to whom treatment has been recommended, in order to determine that the defect has been properly treated.

The New York Physicians' Association is the new name of what was formerly the East Side Physicians' Association. The meetings will be held hereafter at Tuxedo Hall, Madison avenue and Fifty-ninth street.

Mob Crazed Over Cholera.—Inflamed by the

sanitary precautions against cholera, a mob of 300 of the inhabitants of the town of Segni, Italy, marched upon the town hall demanding the release of the detained patients. After sacking and burning the building, they turned their attention to the lazaretto from which they removed the cholera patients, carrying them to their homes on the shoulders of the mob. It was necessary to call out the troops to establish order.

Utah State Medical Association.—The seventeenth annual meeting of this society closed on October 5, with the election of the following officers: *President,* Dr. R. W. Fisher of Salt Lake City; *Vice-Presidents,* Dr. C. E. West of Salina, Dr. E. H. Smith of Ogden, Dr. T. G. Howells of Bountiful; *Secretary,* Dr. W. Brown Ewing of Salt Lake City; *Treasurer,* Dr. H. P. Kirtley of Salt Lake City.

Vermont State Medical Society.—At the ninety-eighth annual meeting held in Burling on October 12 and 13 the following officers were elected: *President,* Dr. Frederick T. Kidder of Woodstock; *Vice-President,* Dr. William Lindsay of Montpelier; *Secretary,* Dr. C. H. Beecher of Burlington; *Treasurer,* Dr. C. F. Dalton of Burlington.

Delaware State Medical Society.—The annual meeting was held at Lewes on October 10, when the following officers were elected: *President,* Dr. Frank L. Springer of Newport; *Vice-Presidents,* Dr. R. G. Paynter of Georgetown, and Dr. J. L. Crossmore of Wyoming; *Councillor,* Dr. James Beebe of Lewes; *Secretary,* Dr. G. W. K. Forrest of Wilmington; *Treasurer,* Dr. Samuel C. Rumford of Wilmington; *Editor of the State Medical Journal,* Dr. A. Robin. The next meeting will be held in Wilmington.

Meeting of Anesthetists.—On October 28 the anesthetists of New York City and vicinity will hold a meeting and dinner at 40 East Forty-first street, New York, preceding Prof. Verworn's lecture on "Narcosis" before the Harvey Society. Details may be obtained from Mr. Harold Sanders, 864 St. John's place, Brooklyn, N. Y.

Removal Notice.—Dr. J. M. Ferrer announces his removal to 24 East Sixtieth Street, New York.

Charitable Gifts.—By the will of the late James Rufus Smith of New York, bequests of $15,000 each are made to the New York Foundling Hospital, the Skin and Cancer Hospital, the Home for Incurables, and St. John's Guild.

By the will of the late Helen M. Stillwell of Whitefield, N. H., formerly of Philadelphia, the sum of $5,000 is bequeathed to the Presbyterian Hospital of Philadelphia to endow a free bed to be known as the Albert H. Stillwell bed.

Obituary Notes.—Dr. Agrippa N. Bell of Brooklyn, N. Y., a graduate of the Jefferson Medical College, Philadelphia, in 1842; a surgeon in the United States Navy during the Mexican War; a member of the national quarantine convention in 1857-60; superintendent of the floating hospital for yellow fever patients in New York Harbor in 1861; inspector of quarantine from 1870-75; in charge of the work of exterminating yellow fever in New Orleans and Memphis in 1879; founder and editor of the *Sanitarian* until 1904; president of the International Congress on Tuberculosis in 1903-04; died at his home from general debility on October 15, aged 92 years.

Dr. Alexander Hugh Ferguson of Chicago, Ill., a graduate of the Toronto University Medical Faculty in 1881, professor of surgery and clinical surgery in the College of Physicians and Surgeons, Chicago; surgeon-in-chief to the Chicago Hospital; a member of the British Medical Association, the American Medical Association, the International Surgical Association, the Academy of Medicine of Chicago, and the Illinois State and Cook County Medical Societies, died at his home of blood poisoning on October 20, aged 58 years.

Dr. George W. Holman of Brooklyn, N. Y., a graduate of the Eclectic Medical College of the City of New York in 1878, died in the Seney Hospital on October 12, aged 85 years.

Dr. Elisha Hopkins of Searsport, Me., a graduate of the Harvard University Medical School in 1854, and a surgeon in the United States Army during the Civil War, died at his home on October 6, aged 82 years.

Dr. Charles B. Wurtz died at Philadelphia on October 8 from heart disease at the age of 52 years. He was graduated from Hahnemann Medical College of Philadelphia in the class of 1880.

Dr. Victor B. Ochiltree of Keokuk, Iowa, a graduate of the College of Physicians and Surgeons of Keokuk in 1883, died at his home on October 11 of cerebral hemorrhage, aged 50 years.

Dr. William H. Malin died at Philadelphia on October 15 at the age of 73 years. He was graduated from the Homeopathic Medical College of Philadelphia in the class of 1858.

Dr. Isaac M. Hightower of Cartersville, Ga., a graduate of the Georgia College of Eclectic Medicine and Surgery, Atlanta, in 1891, died at his home on October 11.

Dr. Harvey Lockwood Finley of Brooklyn, N. Y., a member of the Kings County Medical Society, and of the staff of the Samaritan Hospital, died at his home on October 14.

Obituary.

JOHN HUGHLINGS JACKSON, M.D., LL.D., D.Sc.

LONDON, ENGLAND.

Dr. John Hughlings Jackson, the "father of English neurology," died in London, on October 7, aged seventy-six years. He was born in the County of York and received his early medical education at the York Hospital Medical School. At the age of twenty-four he settled in London, and for the next thirty years engaged in active work at the London Hospital. He was a voluminous writer, and became a pioneer in opening up many unexplored regions in neurology. His work was confined to clinical observation. He was the first to point out the extreme importance of the ophthalmoscope in the diagnosis of diseases of the nervous system. The careful study of convulsive manifestations led him to advance the hypothesis of focal irritation of the Rolandic area, and later of the localization of cerebral functions, an hypothesis that was afterwards confirmed by the experimental investigations of Fritsch and Hitzig, and that received its permanent recognition in the name "Jacksonian epilepsy." In the Croonian Lectures of 1884 he advanced the doctrine of the hierarchy of the nervous centers. He later formulated the modern doctrine of the tonic nature of cerebellar activity. Among the many other contributions which he made to neurology were the definition of apraxia, and the knowledge of temporosphenoidal disease and double hemiplegia.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

THE SCHOOLS OPEN—INTRODUCTORY ADDRESSES, ETC.—MEDICAL EXHIBITION—INSURANCE BILL AND FRIENDLY SOCIETIES—BUST TO A PHILANTHROPIC DOCTOR—OBITUARY.

London, October 6, 1911.

The schools are open, the prizes have been distributed, the dinners eaten, the addresses given, and the teachers and students have set in to work. A drive round to look again at some of the schools shows that at most of them progress is the order of the day. New laboratories and other buildings at once arrest attention, and it may be added that they are an index to other improvements within. Guy's school looks practically rebuilt, but there is yet more to do and it will hardly be finished this season. The pathological laboratory has a completely new building, and chemistry and physics seem equally favored. At the Middlesex, among other improvements, a sanitary tower runs up the building and each ward has a bathing equipment. This hospital sustained a great loss in the death of its chairman, the late Prince Francis of Teck. He was a man of great energy, with business ability and tact, and with sympathy for the afflicted. In three months he cleared off a debt of £20,000 by his personal work. Prince Alexander of Teck has accepted the chairmanship and was present at the distribution of prizes, as was H. R. H. Princess Alexandra.

Dr. Comyns Berkeley, the obstetric and gynecological surgeon, delivered the introductory address at the Middlesex and gave some notes of its history. It began in 1745 in two houses which soon became crowded. It became the first lying-in hospital in England. In it, too, began the first London dental department. In 1754 land was bought and 2,000 guineas acquired for building, to help raise which David Garrick gave two performances. In 1774 the students formed the first medical society and were allowed to meet in the hospital if they found their own candles. In 1793 a ward was opened for the French exiled clergy. How different sounds the statement that £1,000,000 has been spent in connection with the hospital within the secretary's term of office. A wireless apparatus was fitted up on the platform and by it a message of greeting transmitted to the King, who is patron of the hospital.

At St. George's Hospital we had been promised an address on lucidity by the principal of the university, Dr. Miers. Some curiosity was expressed as to what was in store for the students. They were told that medical men needed the ability to express their meaning in written words—the power of mastery over the pen. The style of letters that appeared in the newspapers was often disgraceful. The present methods of teaching were to blame. The study of great authors, often recommended, was no remedy. People should be taught to express themselves clearly in their own language before they thought about style. A generation was growing up which had never been taught to make its meaning clear to anybody. Our grandfathers and grandmothers could do so, and letter writing was in their time more important than it is thought now. They should cultivate lucid writing, a necessary adjunct to lucid thinking. In the interests of science—medical science in particular—if they wished to acquire habits of exact thought they should have constant care in what they wrote to see that its meaning had the desirable quality of lucidity.

At University College Sir William Ramsay distributed the prizes and gave the introductory address. Speaking of research, he remarked that it was unfortunate that men and women were so refractory to experiments. One man's meat was another man's poison and consequently medicine was restricted to one plan of investigation, observations under different conditions were collected and compared. But the drawback was want of control. The conditions were not all known and hence conclusions could not be certain. In contrast purely experimental science admitted more accurate control of conditions. Experiments could be made on lower animals and most of the advances in our time both in medicine and surgery had been by this method. Doubtless without this aid advance might have been possible, but it would have been very slow. They had left behind the speculations of their ancestors and could now acquire experience from demonstrations and from reading. Having acquired knowledge in that way the students' outlook should always be that of the investigator, for with that preliminary knowledge he could seek to solve problems connected with disease while doing his best for his patients and so contribute to the good of humanity.

At Charing Cross Hospital H. R. H. Princess Louise, Duchess of Argyll, accompanied by the Duke, distributed the prizes. An earnest appeal for funds for the equipment of the laboratories, etc., was made by the Duke, who said also that money was needed to set aside as a fund under the control of trustees for the benefit of the hospital. He said further he thought the medical profession was the most interesting of all pursuits for its interest never ended. The possibility of some fresh contribution toward the saving of human life was the enchantment which kept doctors at their work almost as long as they could do it.

At St. Mary's Hospital, Lord Justice Fletcher Moulton distributed the prizes and gave an address in which he pointed out that a longer curriculum would shortly become necessary. He then plunged into the mysteries of opsonins and vaccine therapy and showed he had got up his subject as well as he so often did puzzling cases during his career at the bar. Vaccine therapy, he declared in closing, will make it possible to treat the early beginnings of tuberculosis however numerous may be the cases.

At the Royal Free Hospital (the Women's School) Sir William Butlin delivered an address dealing with research in relation to medicine and to women. He laid down the qualities women required and possessed for research and asked if they possessed them, replying that he thought so—many even in a higher degree than men. One point he confessed he was not certain about—accuracy of detail regarding experiments, than which nothing was more important. He would be asked whether they would ever be able to do more than carry out researches designed for them and in which they had been diverted. This, he said, he did not know. He would not predict what they would do in the way of research, but he would like to see them try.

The Insurance Bill still attracts attention and the Friendly Societies are growing more discontented with the prospect it holds out. The Ancient Order of Foresters, without wishing to wreck the measure, deplores the action of the House of Commons in taking away their right to appoint doctors and say

unless this is allowed they will agitate for a majority of representatives on the health committees. The Independent Order of Odd Fellows is more angry still, and has been using strong language about Mr. Lloyd George. They declared they were determined to make him answer their charges. If they did not get what they wanted they would have nothing to do with the bill and so on. They repudiated the gross misrepresentations about their treatment of doctors. The societies were above the wiles and tricks of party politics. A resolution pledging the conference to use every effort to secure withdrawal of the bill in its present form was carried unanimously.

There was a full attendance at the opening of the medical exhibition organized by the *British and Colonial Druggist* on Monday. It has remained open during the whole week. It is only intended for medical men, of whom all residing within fifty miles have received an invitation. All sorts of medical and surgical appliances were on view as well as a radium emanatorium.

On Wednesday evening Sir William Collins unveiled a bust of the late Dr. Hanley Bean, who died last year at the age of thirty-six. He was a barrister as well as a doctor, and wrote on medicolegal subjects, but being independent of work he devoted himself to promote the welfare of the poor at the East End of London, and there it was that he was honored. The Mayor of Stepney accepted the bust on behalf of the Borough Council.

The death of Louis Stromeyer Little, F.R.C.S., B.A., has taken place after a long illness at the age of seventy. In early life he was surgeon to the London Hospital and lecturer on anatomy as well as curator of the museum. He was also surgeon to the National Orthopedic Hospital, which was founded by his father, the late Dr. Little, who has been called the father of orthopedy, and of which his younger brother, Muirhead Little, is now senior surgeon. The deceased went to the Schleswig campaign in the early sixties and was at the storming of Duppel, where his surgical help was highly appreciated, for there were more than 2,000 wounded. In 1876 he went to Shanghai and became surgeon to the hospital and practised for some twenty years or thereabouts. He then retired, returned to England, and resided in Surrey.

Dr. Joseph Bell, consulting surgeon to the Royal Infirmary, Edinburgh, the Eye Hospital, and the Royal Hospital for Sick Children, and holder of many other appointments in Edinburgh, where he spent his life, has died at the age of seventy-four, full of honors within and without his profession. He was F.R.S. and deputy lieutenant. He had served as examiner at the Edinburgh Royal College of Surgeons. Of the important societies he was fellow and had been president. At the university and the infirmary he was a far-famed teacher. As a clinical teacher he had impressed generations of students with his exactitude in observation. Many were often amazed at the minuteness of the points he grouped together in a diagnosis and how he explained their indications. The manner, appearance, or some slight deviation from the common he would show them, and perhaps from it suggest more than the disease—say the habits or employment of the patient—and he seemed always right. It was not guessing but precise observation. When Conan Doyle was a student he was greatly impressed by this, and when he took to literature he made Bell the original of his famous romance of Sherlock Holmes. The "Manual of the Operations of Surgery" you will doubtless know as a standard textbook which reached many editions.

Dr. James Andrew of Edinburgh, who died on September 19, had suffered for many years from ill health which led to his retirement from active work about two years ago. He graduated in 1868 and was elected F.R.C.P., Ed., 1870, where he served as examiner. He was a member of various societies, physician to the Royal Hospital for Children, and lecturer on skin diseases in his university.

A fine old medical veteran has passed away in Sir Henry Jules Blanc, I.M.S., who has died in Paris at the age of eighty. He was educated at Montpellier, graduated in both arts and medicine in that university, and entered our Indian medical service in 1859. He was assistant surgeon in the China war of 1860 and took part in the Abyssinian mission in 1864, in which he was taken prisoner and kept in chains at Magdala for nearly two years, but afterward joined the British troops and was present at the storming and capture of Magdala. He was awarded the medal with thanks of the government and compensation. Later he became surgeon, senior surgeon, and professor of surgery in the Grand College, Bombay. He retired with the rank of department surgeon general in 1887, was created K.C.V.S. in 1901, and resided for a time at Cannes. He wrote "A Narrative of Captivity in Abyssinia" and various official reports and medical contributions.

Brigade Surgeon Lieutenant Colonel George Grant, I.M.S. (retired), died on October 2 at the age of seventy-seven. He qualified at the Edinburgh College of Surgeons and graduated M.B. at Aberdeen in 1858.

Surgeon-Major John Raby, I.M.S., who saw service in Abyssinia and retired afterward with the recognition of the government, has died from an overdose of a narcotic taken accidentally at Paignton, where he had lived for some years. He was formerly deputy sanitary commissioner in the Dikkan and held other offices.

Dr. Samuel Mills, who was for a long time surgeon to a division of the London police and to the Corps of Commissionaires, has died suddenly at the age of seventy.

A Simple Diet Card and Its Use. F. W. White. M.D.
Phenolsulphonephthalein as a Test of Renal Function. H. Cabot and E. L. Young.
The Bacteriological Examination of Stools as a Measure of Quarantine Protection Against Asiatic Cholera. A. J. McLaughlin.
The Effect Produced by Some Therapeutic Measures on the Different Forms of Leucocytes in Pulmonary Tuberculosis. M. Solis-Cohen and A. Strickler.
A Case of Cerebral Syphilis in a Child Four and One-Half Years Old Cured by Salvarsan. A. W. Fairbanks.

Diet Card.—F. W. White has devised a simple diet card as an aid in applying one's knowledge of the principles of nutrition in the daily use of foods. Its chief value is its convenience. Extreme accuracy is not possible or necessary, and the aim has been simplicity rather than completeness. Its object is to avoid weighing of food and tedious calculations by giving food values in household measures. The author emphasizes the importance of the amount of food as well as its kind. The use of foods has been much less accurate than the use of drugs, and dietary mistakes have been common through ignorance of food values or difficulty in estimating them. A large part of the difficulty for the busy doctor has

been the amount of work needed to estimate the fuel value of a day's food or the amount of carbohydrate, proteid, or fat in it.

Phenolsulphonephthalein Test.—By H. Cabot and E. L. Young. (See MEDICAL RECORD, October 7, 1911, page 748.)

Protection Against Asiatic Cholera.—A. J. McLaughlin refers to the safeguard imposed by the Public Health and Marine-Hospital Service of requiring a bacteriological examination of the stools of all steerage passengers from infected places. The method employed included the administration to the immigrant of a saline purge; the inoculation of a peptone tube with a specimen of stool; the incubation of this tube for six hours; the examination of smears made from the surface culture of the peptone tube, which smears are stained with carbol-fuchsin; if curved organisms are found subcultures in peptone and plates are made on ordinary nutrient agar neutral to phenolphthalein; colonies which have the characteristics of cholera colonies are next examined with reference to the quantitative agglutinating power of a specific cholera serum. Working with this method, ten bacteriologists examined 1,000 specimens in a single day and the complete examination of 1,200 stools was concluded within 48 hours. The immigrants from infected districts had been examined bacteriologically before leaving Italy so that the chances of finding carriers were small. Quite a number of vibrios were isolated, but none agglutinated with cholera serum, although some were morphologically indistinguishable from true cholera vibrios.

Leucocytes in Pulmonary Tuberculosis.—M. Solis-Cohen and A. Strickler state that in the differential leucocytic count one has a means of studying more exactly than in any other way the effect produced by therapeutic measurts in patients with pulmonary tuberculosis. It is impossible to state definitely, however, whether the changes observed in the leucocytic pictures are produced directly in the blood, or result indirectly from the change in the general condition of the patient caused by the measure employed. It would seem from the few cases studied that: (1) Bier's suction hyperemia in cases suitable for this treatment causes an increase in the proportion of lymphocytes and of polynuclear cells with one and two nuclei. (2) Applying fly blisters every five days and allowing the serum to become absorbed causes an increase in the proportion of polynuclear cells with one and two nuclei and in most instances an increase in the proportion of lymphocytes. (3) Iodine in the form of iodoform administered by the mouth causes an increase in the proportion of polynuclear cells with one and two nuclei. (4) Creosote given in the form of the carbonate as a rule causes an increase in the proportion of lymphocytes and of polynuclear cells with one and two nuclei. (5) Nuclein seems to cause an increase in the proportion of polymorphonuclear neutrophiles. (6) The effect produced in the blood by many therapeutic measures is not as a rule maintained indefinitely, but only for a variable period, averaging about a month.

Salvarsan and Cerebral Syphilis in a Child.—A. W. Fairbanks reports a case of cerebral syphilis in a child aged four and a half years, cured by one injection of 0.3 gram of salvarsan.

The Treatment of the Portal of Entry of Systemic Diseases. G. Wilson.
A Brief Résumé of the Newer Teaching of Gastrointestinal Diseases. M. I. Knapp.
The Recurrence of Scarlet Fever, with Report of a Case. J. P. Crozer Griffith.
Some of the More Important of the Legal Aspects of the Practice of Medicine. H. M. Friedman.
On the Use of Nuclein Solution in Surgery. H. J. Achard and H. H. Redfield.
Complications Following the Submucous Operation Upon the Nasal Septum. I. H. Alexander.
A Few Suggestive Experiments for a Cutaneous Reaction for the Diagnosis of Syphilis; Preliminary Theoretical Report. M. J. Schoenberg and E. Burchill.
The Rôle of Extensor Toe Reflexes in Neurological Diagnosis. T. B. Throckmorton.

The Portal of Entry of Systemic Diseases.—G. Wilson calls attention to the possibility of good that might result from searching for, and treating, a focus of suppuration that might be a fundamental cause of such diseases as acute articular rheumatism, endocarditis, chorea, and the rheumatic diseases of the eye. It is generally agreed to-day that the first need in the treatment of gonorrheal rheumatism is to cure the urethritis or prostatitis, and the author believes that the portals of entry of other diseases during the acute stages should be cleansed with mild antiseptics.

Gastrointestinal Diseases.—M. I. Knapp believes that gastritis is a relatively rare disease; that mucous colitis and atony of the stomach are meaningless terms; that bronchial asthma is caused by pyloric insufficiency; and that there is a distinct class of diseases characterized by the presence of organic acids in the stomach.

Recurrence of Scarlet Fever.—By J. P. Crozer Griffith. (See MEDICAL RECORD, July 29, 1911, page 249.)

Legal Aspects of Medicine.—H. M. Friedman presents a brief review of this subject.

Nuclein Solution in Surgery.—H. J. Achard and H. H. Redfield report a series of eight cases in which nuclein solution was applied as a dressing to infected wounds. In every instance healing occurred promptly and without suppuration.

Submucous Operation on Nasal Septum.—I. H. Alexander reports as complications of this operation three cases of severe infection, two ending fatally in acute purulent meningitis. The author has also seen many cases of acute catarrhal otitis media and acute purulent otitis media, several cases of acute mastoiditis treated by operation and one case of double mastoiditis. The author believes that, although the benefits of the submucous operation are well recognized, nevertheless conservatism in the selection of our cases should always be the rule; that complications do arise and are sometimes very serious; and that, no matter how simple some cases appear, infection may take place and change the entire subsequent course of the case.

Cutaneous Reaction in the Diagnosis of Syphilis.—M. J. Schoenberg and E. Burchill suggest that, even though their experiments have so far been negative, there may yet be discovered a local reaction of the skin to the syphilitic virus.

Extensor Toe Reflexes.—T. B. Throckmorton concludes that extensor toe reflexes are never found in health and are pathognomonic of pathological change. A tendency for the great toe to extend is usually present by the percussion method even when Babinski's sign is light or indeterminate. Replacement of one reflex by another may sometimes occur.

Thrombosis of the Mesentery Causing Gangrene of the Ileum. R. W. Wakefield.
An Avoidable Accident During Lumbar Puncture. W. F. Lorenz.
Opsonotherapy in a Case of Puerperal Sepsis. W. C. Wolverton.

Extraabdominal Multilocular Ovarian Cyst.—T. S. Cullen reports the case of a partly solid, partly cystic tumor of the ovary, lying external to the abdominal muscles, the tumor and its surrounding sac being covered with a small amount of adipose tissue and skin. The pedicle of the tumor passed through a hernial ring to the outer side of the right rectus and obliquely across the lower abdominal cavity to what corresponded to the normal insertion of the right utero-ovarian ligament.

X-Ray Diagnosis of Gastrointestinal Conditions.—By G. R. Satterlee and L. T. Le Wald. (See MEDICAL RECORD, July 8, 1911, page 98.)

Cervical Implantation of the Placenta and Rupture of the Uterus.—C. Goodman reports a case of uterine rupture which he believes was caused by cervical implantation of the placenta.

Rupture of the Kidney.—A. J. Mayer and A. Nelken report a fatal case of subparietal rupture of a solitary kidney.

Blood-Vessel Forceps.—B. M. Bernheim has devised a delicate pair of forceps with a small, polished metal knob about the size of an ordinary pin-head on each end. These knobs enable one to grasp the vessel firmly without doing the slightest damage to the intima.

Tumor of Bladder.—W. H. Dukeman reports a case of vesical epithelioma successfully removed by intraperitoneal cystotomy.

Hemorrhagic Erosions of the Stomach.—(By N. W. Jones. See MEDICAL RECORD, July 1, 1911, page 47).

Bubonic Plague of Ground-Squirrel Origin.—G. W. McCoy gives a history of the experience with rural bubonic plague of ground-squirrel origin in California. There were three clinical types: the severe acute, the mild acute, and the subacute or pyemic. No case of primary pneumonic or primary septicemic plague from ground-squirrel infection has come under observation.

Pneumonic Plague.—R. P. Strong and O. Teague conclude that during normal and dyspneic respiration of primary pneumonic plague patients plague bacilli are not usually expelled by means of the expired air. During the coughing of such patients, even when sputum visible to the naked eye is not expelled, plague bacilli in large numbers may become widely disseminated into the air surrounding the patient. As to the distance from the patient that the air may be infected by droplets containing plague bacilli, this varies with the strength of the cough, the amount of mucous in the throat and larynx at the time, and the currents of air in circulation in the ward. The idea that infection of doctors, nurses, and attendants in plague hospitals is caused entirely by particles of sputum expectorated by the patient and visible to the naked eye is erroneous. The wearing of masks and the proper covering of any surface of the skin where fresh abrasions are present are important personal prophylactic measures in pneumonic plague.

Control of Plague.—R. Blue, E. E. Heg, and W. F. Snow state that, while this disease has been controlled in San Francisco, large sections of the central and coast counties of California are still infected so far as rodents are concerned and several human cases have occurred directly traceable to these animals. The methods for the control of the present situation should include the following measures: (1) The prevention of spread from rural to urban rodents by limiting the chances of contact and interchange of ectoparasites between the two. This suggests (*a*) the maintenance of squirrel-free zones around the centers of population; (*b*) prohibiting the marketing or traffic in rodents; (*c*) general rat destruction in the cities. (2) The prevention of a wider spread among rural rodents and the ultimate invasion of the Eastern States by such means as the following: (*a*) destruction of known enzootic foci in the various countries; (*b*) general rodent extermination throughout California and the nearby States.

Control of Plague.—R. Blue recommends that a general extermination of rodents of the families *Sciuridæ* and *Muridæ* should be systematically carried out in all Pacific and Mississippi Valley States, and he also suggests thorough supervision of foreign commerce to prevent the introduction of plague from without.

Control of Poliomyelitis.—W. H. Frost, H. W. Hill, and S. G. Dixon recommend the isolation and screening of patients known or suspected, the thorough disinfection of their excreta, of articles used by them and their attendants, and of the premises where cases occur. While quarantine of persons in contact with patients does not seem as yet justifiable, it is recommended that members of patients' families be excluded from schools during the period of the patients' isolation and during the possible incubation period of a new case, *i.e.* for two weeks following the end of the last exposure to the presumptively contagious person. The daily administration of hexamethylenamin seems to offer some hope of reducing the susceptibility in persons exposed to the disease.

Control of Contagion.—H. Spalding, I. D. Rawlings, and H. Cohen discuss the methods of controlling contagion through the cooperation of physicians and nurses.

Control of Smallpox.—H. Spalding discusses the control of smallpox in municipalities, and H. M. Bracken discusses its control in rural districts and small municipalities.

Public Health Exhibits.—F. B. Wynn advocates the establishment of permanent health exhibits.

Psychological Aspect of Refraction.—S. L. Ledbetter states that if all persons were alike in their mentality and habits of thought refraction would be reduced, in a measure, to a simple question of accurate observation and correct measurements. Such, however, is not the case. The individual has to be considered with all his eccentricities and idiosyncracies.

Intrauterine Ophthalmia Neonatorum.—W. A. Newman Dorland reports a case the points of interest in which are the early rupture of the amniotic sac one week prior to the onset of the labor pains; the apyretic course of the mother's case in the presence of a virulent vaginal infection; and the infection of the child's eyes during the week subsequent to the rupture of the membranes while the fetus was still *in utero*.

Mesenteric Thrombosis.—R. W. Wakefield reports a case of this condition followed by gangrene of the ileum in a man aged 60 years. Operation was successful.

Breaking of Needle During Lumbar Puncture.—W. F. Lorenz reports a case of this accident, and suggests that this can be avoided if means are taken to prevent a sudden extension on the part of the patient.

Vaccine Treatment of Puerperal Sepsis.—W. C. Wolverton reports a case of puerperal sepsis treated successfully by means of stock vaccines of *Streptococcus pyogenes* and *Staphylococcus pyogenes aureus* and *albus*.

The Lancet.

Research in Medicine and Women in Research. Sir Henry T. Butlin.
Lucidity. H. A. Miers.
The Middlesex Hospital of To-day and Yesterday: a Bird's-Eye View. C. Berkeley.

Consumption and Order of Birth. W. C. Rivers.
Note on Two Cases of Tumor of the Prefrontal Lobe in Criminals; with Remarks on Disorders of Social Conduct in Cases of Cerebral Tumor. W. C. Sullivan.
Strangulation by Volvulus in an Abnormal Sac Lying Within the General Peritoneal Cavity. R. Lawford Knaggs.
True Bradycardia in Association with Uremia. E. E. Laslett.
Open-Ether Anesthesia: Some Improvements. J. Robertson.

Research in Medicine and Women in Research.—Sir H. T. Butlin contrasts the two methods of research, observation and experiment, and discusses the questions of the utilitarian object and the cost of research. The qualities needed in an investigator are personal cleanliness; cleanliness of habit; continued industry; patience, perseverance, and a determination to pursue the research to the end; extreme care in observation and strict attention to detail; careful recording of observations, which should be done at the earliest possible moment; thorough belief in the importance of the particular research, amounting even to enthusiasm; and conscientiousness. Women possess these qualities, but there is one quality in which they are deficient, namely, the ability to make accurate records of observations and experiments.

Lucidity.—H. A. Miers advocates in the interest of medical science the cultivation of the habit of exact thought and of lucid expression.

The Middlesex Hospital.—C. Berkeley presents a bird's-eye view of the history of this hospital since its foundation 166 years ago.

Tuberculosis and the Order of Birth.—By W. C. Rivers. (See page 889.)

Tumor of the Prefontal Lobe in Criminals.—W. C. Sullivan reports two cases of brain tumor in which symptoms of disorder of social conduct appeared to have been among the earliest indications of the impairment of mental function.

Volvulus.—R. Lawford Knaggs reports a case of intestinal strangulation caused by volvulus in an abnormal sac lying within the general peritoneal cavity.

Bradycardia in Association with Uremia.—By E. E. Laslett. (See page 890.)

Ether Anesthesia by the Open Method.—J. Robertson describes his method of administering ether as follows: The patient is given a deep subcutaneous injection of one dose of omnopon an hour previous to operation. When the patient is placed on the operating table he is in a slightly sleepy condition. The mask is placed over the nose and mouth, and in three or four minutes, as a general rule, after the administration of from half to one ounce of ether the patient is snoring comfortably and is absolutely lax. No difficulty is experienced in maintaining this condition with another half-ounce of ether for an hour. The pupils are slightly contracted and react to light. In some cases there is slight and temporary divergent strabismus. The conjunctival reflex is absent. The face is slightly flushed a pink color. The pulse is full and steady. The respirations are slow and deep, perhaps 12 to 15 a minute. There is no mucus production in the throat, and there is neither spasm nor tremor. After a three hours' operation the patient is practically in the same condition as at the start.

British Medical Journal.

October 7, 1911.

Transplantation of a Segment of Small Intestine to Repair the Resected Sigmoid Flexure. W. S. Fenwick.
The Dermatitis Produced by East Indian Satinwood (*Chloroxylon Swietenia*). J. T. Cash.
Cystic Ovary in the Pelvis. E. L. Gowlland.

Transplantation of Segment of Small Intestine.—W. S. Fenwick reports the case of a man aged 51 who suffered from chronic intestinal obstruction caused by a carcinoma of the sigmoid flexure of the colon. The small intestine was greatly hypertrophied and distended, and such was the congestion of the intestinal vessels that the abdominal cavity contained a considerable quantity of blood-stained fluid. The colon above the growth was explored and found to have a very short mesentery not more than 2 inches in length. The patient's condition was too grave to allow of an attempt at resection, and indeed the distension of the intestines rendered it impossible. Accordingly the mid-line wound was closed in layers, an iliac colotomy performed, and a Paul's tube inserted. Owing to the shortness of the mesentery, great difficulty was experienced in bringing the bowel to the anterior abdominal wall. Next day the colotomy acted well, and subsequently three to four times daily. Ten weeks later a second operation was performed. The mass was cut away with a V-shaped portion of mesentery in which enlarged glands could be felt. A loop of ileum fairly low down was taken, clamped off, and divided with a portion of its mesentery, and transplanted into the gap in the colon, the anastomosis being effected with the aid of two Murphy buttons. The operation was successful. Subsequent attempts were made to close the colotomy opening but without complete success. The patient gained rapidly in weight and strength, and recovered the power of normal defecation.

Dermatitis Produced by Satinwood.—J. T. Cash refers to outbreaks of dermatitis in wood-working departments of shipyards on the Clyde which were traced to the irritant action of satinwood. He reports the results of his experimental investigations which show that the alkaloid chloroxylonine, extracted from the wood, is an irritant and is capable of causing dermatitis. Two resins and an oil contained in the wood are capable of arousing dermatitis in those who have been rendered abnormally susceptible by chloroxylonine action.

Cystic Ovary.—E. L. Gowlland reports a case of multilocular cystic ovary in a patient aged 68 years in which the following points of interest are noted: (1) The sudden onset of complete retention of urine. No advice had been sought till three days before the operation. (2) The difficulty of diagnosis due to the extreme hardness of the tumor. On commencing the operation the author expected to have to perform supravaginal amputation for impacted fibroid of the uterus. (3) The denseness of the adhesions. After freeing the tumor, the posterior uterine wall was quite raw and ragged. (4) The contents of the cyst were sterile.

Berliner klinische Wochenschrift.

October 9, 1911.

Anemias of Nurslings.—Finkelstein states that even apparently healthy babies are often pale, with relatively low hemoglobin values. The latter range from 60 to 70 per cent., the red corpuscle count being high in porportion. Pseudoanemia is the term applied to pallid children with normal blood values. Children are often born with deficient iron in their blood; and if the iron at birth is normal or in excess, this slowly disappears from the organism unless food rich in iron is given. Some authorities claim that under normal circumstances the newly-born child is much richer in iron than is the adult because it is destined to subsist for months on milk, which is poor in iron. There is a so-called chlorotic type of anemia in the nursling which responds readily to iron medication. The hemoglobin in these cases may sink below 50 per cent. The author does not like the term chlorotic anemia and would substitute for it oligosideremia, meaning poverty in iron. This type is doubtless due to congenital insufficiency of the spleen and other blood-making organs. Another type of nursling anemia is the so-called anemia pseudoleucemica infantum, a condition described fully in textbooks. In addition to the types just enumerated, which are primary, we have secondary anemias, such as result from syphilis and other constitutional affections, diseases of the gastroenteric organs, etc.

Compounds of Bromides and Urea in Epilepsy.—Fischer and Hoppe have introduced into the therapeutics of epilepsy a combination of calcium bromide with urea. The latter component alone should require attention. It is said to diminish the toxicity of bromine. Calcium is chosen before other metals because as a natural constituent of the body in large quantities it enters largely into metabolic processes. It is necessary for the maintenance of the integrity of the blood and of cardiac activity. Urea administered as a drug may at first sight seem contraindicated in a convulsive disease with possible N retention; but the authors assert that when given intravenously urea promotes the elimination of tissue urea. The claim is made that the combination is especially indicated in defective excretion, weak cardiac action, possibility of autointoxication, and finally when the patient has the spasmophilic diathesis, the latter suggesting calcium starvation.

Treatment of Arteriosclerotic Gangrene by Arteriovenous Anastomosis.—Glasstein cites the recent study of this subject by Monod and Van Verts, who compiled 26 cases, of which 16 were for severe gangrene. Of the series of 10 milder cases in which the gangrene was just beginning two cases resulted favorably (20 per cent.). Of the 16 operations for severe cases but one ended successfully. The author reports in detail a favorable result in a case of beginning gangrene, which makes 3 recoveries in 11 cases. The patient had already lost a leg from amputation for beginning gangrene three years before, so that the operation for anastomosis seemed justifiable, since in case of failure amputation still held out a prospect of cure. The intervention was made in Scarpa's triangle, the peripheral end of the femoral artery being anastomosed with the central end of the femoral vein. The arterial blood was forced into the empty vein, which at once dilated. The limb was placed in a splint. The operation was a complete success, the gangrenous process being arrested. Carrel's technique doubtless contributed to the good results. This investigator now prefers the termino-terminal anastomosis to the latero-lateral method employed in the author's case.

October 3, 1911.

Warmed Ether and Chloroform Vapor for Narcosis.—Läwen writes monographically on this subject, giving the history of the principle involved. Among sponsors for the latter are a number of Americans. The author, while far from claiming that warmed vapor can prevent postoperative pneumonia, believes that its tendency is in this direction, and he employs the method both in prolonged intervention in the abdominal cavity, in other localities in which the operative field is large, and finally in all cases in which shock and hemorrhage have already occurred. The warmed narcotic vapor is administered alternately with warmed atmospheric air.

Uzara, a Native African Remedy for Diarrhea.—Gürber describes this new natural resource in great detail. The credit for bringing it to the attention of the profession is due to Hopf, who sent samples to Marburg for study. The pharmacodynamic principles are extracted by alcohol. Two of these appear to be glucosides, while a third is evidently of a different character. The nature of these principles will be discussed in another article. They appear to represent a multifold activity and the ability to control diarrhea and dysentery in a manner suggesting the activity of opium in this direction is but one example. It goes without saying that so valuable a remedy has been promptly commercialized, but there seems no reason why it should not come into the ordinary trade channels.

Steinmann's Nail Extension in the Treatment of Fractures.—According to Koerber this resource was first made public in 1907. The limbs are placed in the extension posture. Nails are introduced into holes made near the break and the broken ends wired together. The nail holes are made in one of three ways, viz., by driving the nails directly into the bones, by a gimlet or auger, or by an electric drill. When the nails are removed an iodoform pencil may be inserted into the holes. The author has tested the method in 70 cases of fracture of the lower extremity. There were all the customary varieties: simple, complicated, compound, etc., and both old and recent fractures were comprised. The breaks were seated in all the ordinary localities, including the neck of the femur. Among the cases were also artificial solutions of continuity—osteotomies. The author has analyzed his results from a variety of standpoints. Pain incidental to inserting and removing the nails was present in nineteen cases but it never became necessary to remove the nails prematurely. These pains would naturally prove a drawback to the method, and the author considers them minutely. In five cases they formed a notable handicap, persisting for months. Usually, but not invariably, was this type of pain associated with local bone infection. The danger of infection is twofold, viz., early and late. The former develops directly after the intervention, and this primary infection was in evidence in but three cases, none of which was serious. Secondary infection occurs after the third week, and is much more serious. Three were one case of fatal sepsis, one of phlegmon, and several of abscesses. The author also lost a patient with delirium tremens and another from fat embolism due to the nature of the fracture. The author naturally pronounces against the method under all ordinary circumstances and only recommends it in extreme cases—old ununited fractures, certain complicated fractures, osteotomies, etc.

October 5, 1911.

Exhibition of Tuberculin per Os.—Möllers and Heinemann reach the following conclusions after extensive investigations into this subject: It is practicable to administer tuberculin in capsules, provided the latter escape the destructive action of the gastric juice. *In vitro* pepsin and trypsin can so damage tuberculin that it no longer can produce its characteristic results in the animal organism. The patients who are most sensitive to the action of tuberculin do not in most cases show any reaction, febrile, general, or focal, when the drug is given by the mouth. Even when given per os in high doses there is no evidence of the formation of antibodies in the blood serum. It therefore follows that while some tuberculin may be absorbed in the intestine the method of administration per os cannot be compared at all with the subcutaneous method; and that neither for diagnosis nor treatment does it hold out any material hope when given in the first-named manner.

Inflammatory Tumors of the Abdominal Wall.—Heymann refers to an apparently new surgical affection described by Schloffer at the Surgical Congress of 1908. This was a chronic inflammatory tumor developing in the scar of a hernia operation. It was invariably found by the discoverer that the tumor had formed about a nucleus of a piece of sublimate silk. The appearance and mode of growth of these tumors had suggested malignancy. Other surgeons had noted the occurrence of the same growths after appendicitis operations. It also appeared that other growths pathologically and clinically similar to the preceding could arise after operations involving laparotomy, yet without a foreign body as a nucleus; while in other cases the growths originated without a preceding operation. The author describes a case which appeared to have an embryonal origin. It must be assumed that all these inflammatory, pseudomalignant growths were due to infection of a mild degree of virulence, which had it been more severe would have produced an abscess.

Insurance Medicine.

Remarks Upon the Medico-Actuarial Investigation.—Arthur Hunter says that the chief reason for making a medico-actuarial investigation are probably: (1) that the insurance companies desire a more uniform practice in the selection of certain types of risks; (2) that actuarial and medical directors desire more information on borderline and semi-hazardous or hazardous risks than has been derived from the specialized investigation. With regard to the other reasons for the medico-actuarial investigation, the shortcomings of the specialized investigation were principally the following: (*a*) a lack of homogeneity in certain of the groups of occupations; (*b*) a lack of essential information regarding certain of the classes involving medical impairments. Under (*a*) might be mentioned the grouping of distillers and employees in the same class; also the great diversity of the risks in the class consisting of those "exposed in occupation to electricity." Class (*b*) might be taken as including those who had taken the cure for or had recovered from intemperance. No information was required regarding the time elapsed since the cure was taken or with regard to subsequent habits. Another class might be mentioned, those who had had syphilis. In the new investigation all these defects have been borne in mind.

All the companies invited to take part in the investigation will furnish their data on the twenty-six medical impairments, while many of them will include the optional impairments. Sufficient information ought to be obtained to enable the companies to have a more uniform standard of medical selection. As to occupations, the results of the investigation will enable the actuaries to prepare plans for treating people engaged in hazardous occupations more in accordance with the circumstances than has been possible in the past. One of the most important results which it is hoped to achieve is the determination of the influence of build upon longevity, especially among overweights. Another important result will be the more equitable treatment of applications from women.

There will be many difficulties in gaining these results. The expected deaths present the first and simplest difficulty. So much labor would be spent in procuring exact data that the committee decided to experiment with a view to grouping the ages. After making use of the statistics of the Mutual and the New York Life, the Committee decided to employ quinquennial age-groups from 15 to 49, a quadrennial age-group from 50 to 53, and triennial age-groups thereafter. The next problem to be solved was the division of the occupations and medical impairments with respect to the nine build groups. The committee decided that the occupations should be divided into three groups, underweights, normal weights, and overweights. Medical impairment was another difficult question. The medical directors of the committee felt that the types involving tuberculosis in the family record or in the personal history should be treated with great discretion. They especially desired to study the effect of lightweight combined with a family record of tuberculosis. It was decided to have subdivisions for each underweight-build group and to divide the overweights into two classes only. Other medical impairments were divided into three groups of overweights, normal weights, and underweights. As to the further grouping of medical impairments necessarily very large, the committee endeavored to combine the lesser groups and to consider the matter. The four groups of syphilis will be divided into three build groups and subdivided into the nine groups covering number of attacks and time elapsed since the attack, making 108 groups in all.

Two more questions to be solved are the relation of abdominal girth to chest expansion and the grouping of those who have two or more impairments. In the specialized investigation when a man had two or more impairments the experience on his life was put into two or more corresponding groups. In the new investigation it is hoped that means will be found to simplify that method.—Proceedings of the Twenty-first Annual Meeting of the Association of Life Insurance Directors.

The Interpretation of Murmurs.—J. F. Halls Dally states that diastolic murmurs, and by these he means the aortic and early mitral varieties, are almost invariably persistent and organic. Presystolic murmurs, however, are not pathognomonic of mitral disease, and, except when they occur in aortic disease, are a sign, rather, of compensation than of failing compensation. The rule is that murmurs resulting from stenosis of any orifice are best heard with the patient standing; if the result of insufficiency, they are best heard when the patient lies down. But one must bear in mind that, on lying down, stenotic murmurs may diminish in intensity when the heart muscle is failing badly. With an apex-beat in the normal situation and regular in rhythm, the auscultatory phenomena may be practically disregarded.—*The Practitioner*, September, 1911.

Pathology of the Order of Birth with Special Reference to Tuberculosis.—W. C. Rivers presents an important study of this subject, based upon his own observations and upon a review of the literature. He had noticed in examining the case histories of a large number of patients at a sanatorium that a considerable proportion of these were eldest-born children. The material was subjected to mathematical analysis by Karl Pearson, who concluded from the figures that both first and second-born offspring appear subject to consumption at a very much higher rate than younger members of a family. Similar analysis of 500 cases of tuberculosis reported by Brehmer revealed the same results and also the fact that there is an excess of tuberculosis among the sixth-born. Records of several generations of the populations of South German villages revealed to Riffel that first-born children show a larger proportion of tuberculosis than any of the rest. The author's own material included 353 cases. In reviewing the literature of what may be called the pathological aspect of primogeniture he gleans the following observations: Sir A. Mitchell found among 443 idiots and imbeciles that 31.1 per cent. were first-born. This observer concluded that idiocy is more likely to occur among first and latest pregnancies than among others. Matthews Duncan found that first-born children in Scotland are shorter and lighter than others, but traces this to the influence of early age of the mother. Carman after examining 1,507 Michigan school children found that in general sensitiveness to pain decreases in order of birth. Wells, studying data furnished by trained observers and by teachers of school children in California, gives curves showing, with minor sex differences, first-born children superior to others in weight, height, association time, discrimination, voluntary motor ability, natural mental ability, neatness, and deportment. Macdonald stated that of fifty-three university students the first-born were more sensitive to pain than the second-born. Dugdale is quoted by Havelock Ellis as finding that criminality favors the first-born child. Beeton and Pearson in a paper on the inheritance of the duration of life studied the pedigree records of Quakers. The authors found that the elder adult sister and adult brother live on an average four years longer than the younger adult sister or brother. Heron's study of Urquhart's 331 family trees of lunatic asylum patients showed excess of insanity among the four eldest, and deficiency in the remainder. Pearson in his Boyle lecture quoted the following findings, namely, that the elder-born are more liable to pulmonary tuberculosis and insanity—and, on the authority of Goring, added

a third, criminality. There remain two more medical observations: that of Davidson, who found ten out of nineteen cases of congenital pyloric stenosis to be eldest children; and that of Hunter, who among idiots and their parents described specially heavy incidence at either end of the family. In summing up his study of this subject Rivers concluded that an innate tendency to consumption, a soil intrinsically suitable to the tubercle bacillus, and not the result of weakening by other disease, is an idea which has always had support. Bacteriological work may have limited the influence to be properly assigned to this predisposition; nevertheless, the theories of the *habitus phthisicus*, as stenosis of the upper thoracic aperature, the frequency of a small heart, of a condition of underweight, of supernumerary nipples and of nasal defects have never been confuted. Eldest-born incidence might unite all these as coordinate degenerative manifestations; and eldest-born incidence apparently disposes of the objection, first advanced by Cohnheim, that the *habitus phthisicus* is the result of an already existing tuberculous infection. These facts have an obvious bearing upon prophylaxis and upon life and sickness assurance.—*The Lancet,* October 7, 1911.

Bradycardia.—E. E. Laslett reports a case of uremia in which an extremely slow pulse was a prominent symptom. He notes that an infrequent pulse is occasionally associated with some forms of toxemia, particularly those which accompany catarrhal jaundice and chronic nephritis. An infrequent pulse may be due to three different causes: (1) the regular occurrence of extra-systoles not perceptible to the finger on the pulse (coupled rhythm); (2) heart block, partial or complete; and (3) slowing of the whole heart. It is only since the introduction of the graphic method of studying heart affections that it has become possible to distinguish certainly between these distinct conditions. It has been ascertained that the slow pulse of jaundice is most often due to a coupled rhythm, much less commonly to a slowing of the whole heart. As regards the pulse in nephritis, little is at present known either as to its nature or its cause. It is not yet considered as proved to be due to uremic poisoning, and Vaquez and Esmein, in their report on bradycardia to the French Medical Congress last year, stated that the question needed further research.—*The Lancet,* October 7, 1911.

The Life Insurance Examiner's Responsibility.—A paper with this title was read before the American Association of Medical Examiners, at Los Angeles, Cal., June 1911, by Dr. Allison Maxwell of Indianapolis, Medical Director State Life Insurance Company. The necessity for medical examiners in life insurance companies is pointed out, and attention is also drawn to the fact that the life insurance companies are dependent upon their examiners, largely, to keep down the mortality and preserve their very life. This is the strongest argument for the need and careful selection of medical examiners of integrity and professional ability. His indeed is a position of great responsibility. In dealing with candidates for insurance, while he is compelled to be frank, at the same time he must exhibit courtesy and tact. Although the medical examiner must be loyal to the company he should be mindful of the agent and prompt to assist him in completing the examination. The examination itself should be careful in all its details. Of course, it is well known that there are other points to be looked after besides those asked on the blank. There may be something in the candidate's gait; his breath, as the odor of the diabetic; his furtive glance, something that suggests fast living and burning the candle at both ends. Over and above the physical examination the medical examiner can frequently give important information to the company under what may be termed the moral hazard. There are many things which emphasize the moral hazard about which the examiner may privately write to the home office. For instance: an applicant may lead a notoriously immoral life, which means a short life, or a man may lead an indolent life, without any legitimate business or means of support; or the opposite, a man may work eighteen hours out of the twenty-four and tax his mental and physical powers to their limit to gain wealth, or fame, or both. The various hazardous occupations on many occasions are not given as the real vocation of the applicant, and where the medical examiner knows that the latter is engaged in two occupations, one of which may be dangerous, of course he will give this information to the medical department. Maxwell states his belief that, as a rule, medical examiners for life insurance companies are the most honorable and best educated men in the community. As a proof of this he points to the decrease of tuberculosis as due to better examiners and better preventive treatment.—*Lancet-Clinic,* September 9, 1911.

Tuberculosis and Insurance.—Victor C. Vaughan, Jr., says that tuberculosis is primarily a contagious disease, but probably it takes rather a long exposure before an individual becomes infected. This is why family history is so important in this connection. Yet applicants who are not underweight and who have attained an age of 40 or over are frequently insurable as standard risks in spite of a family history of tuberculosis. Applicants closely associated with consumptives may be worse risks than those giving a family history of the disease; for example, a husband, whose wife is consumptive. Such refinements of diagnosis as the *x*-ray or the tuberculin tests are impracticable in routine insurance work, but an accurate record of the temperature and pulse should be made by every examiner. Applicants with tuberculous family history should be examined in the afternoon, so that slight rise in temperature and pulse may not be missed. *Proceedings of the Medical Section, American Life Convention, New Orleans,* February, 1911.

Rating of Hazardous Occupations.—W. S. Kendrick said that the general public thinks that the life insurance companies have formulated fixed and uniform standards for selection of their risks. Yet reliable and comprehensive medical data on the subject of medical selection are quite lacking. Such a table has been produced in reference to one hundred and forty-four hazardous occupations, the data being obtained from twenty-six different companies. In only one case, the occupation of house carpenter and joiner, did these companies agree unanimously. A "Bureau of Research" should be established by the insurance companies to gather all such data, by which all may benefit. Such investigation lies in the scope of the medical departments.—*Proceedings of the Medical Section, American Life Convention, New Orleans,* February, 1911.

Pneumonoconiosis in Stonecutters.—Among marble workers and stone cutters the death-rate from consumption is nearly five times greater than it is among farmers, planters and farm laborers. The excessive mortality among the stone and marble workers is due to the dangerous character of these occupations. Men who work at these trades must necessarily inhale considerable quantities of dust that is especially irritating and injurious to the lungs and respiratory tract. It is also extremely difficult to provide protective devices outside of the moistened sponge respirator worn over the mouth and nose. Few workers, however, will wear them on account of the discomfort they cause, even though they are fully aware of the danger to which they are exposed. In many of the dust-producing industries methods are employed to arrest and remove the dust at the points of origin and carry it away from the operators. And while much has been accomplished along the lines of dust removal in industrial establishments, the conditions in many of the trades are still deplorably bad. In fact, it may be safely asserted that in most of the States in the Union factory sanitation is yet a long way below the standard that should prevail were it to be carefully considered from both the economic and health standards.—*Bulletin Chicago School of Sanitary Instruction.*

Book Reviews.

Laboratory Studies in Tropical Medicine. By C. W. Daniels, M.B. Camb., M.R.C.P. Lond., Lecturer on Tropical Diseases at the London Hospital; formerly Director of the London School of Tropical Medicine; Director of the Institute for Medical Research, Federated Malay States; Member of the Royal Society Malaria Commission in India and Africa, and in the Medical Service of the Colonies of Fiji and British Guiana; and H. B. Newham, M.R.C.S. Eng., L.R.C.P. Lond., D.P.H. Camb., D.T.M. & H. Camb., Director, formerly Demonstrator, London School of Tropical Medicine. Third edition, thoroughly revised, with many new and additional illustrations. Price, $4.00 net. Philadelphia: P. Blakiston's Son & Co., 1911.

The various improvements which have been introduced into the third edition of "Daniel's" serve to keep this volume on a very high level. It is still the best short practical guide for laboratory work in tropical medicine. A great variety of subjects are fully treated. Especially good chapters will be found on the staining and examination of the blood, on the various blood parasites and on the identification of parasitic insects, such as mosquitoes and flies. Elaborate directions are given for breeding and transporting mosquitoes for experimental purposes. Recent discoveries as to the transmission of plague and similar diseases have necessitated the introduction of a good deal of material concerning the different species of fleas. An excellent diagnostic chapter is that on the examination of feces for parasites and the classification of the parasites themselves. A short chapter contains the elements of bacteriology and another portion is devoted to water analyses. The colored plates are extraordinarily valuable, not only on account of their careful drawing, but because of the beautiful manner in which the color of the stains employed has been reproduced.

The Bellevue Hospital Nomenclature of Diseases and Conditions, with Rules for the Recording and Filing of Histories. Compiled by the Committee on Clinical Records, composed of Robert J. Carlisle, M.D., Warren Coleman, M.D., Thomas A. Smith, M.D., Edmund L. Dow, M.D. Adopted by the Board of Trustees, 1903. Revised and made to conform to the International Classification, 1911. New York: Copyright by the Board of Trustees of Bellevue and Allied Hospitals, 1911.

Medical nomenclature of the present day, in the absence of any authoritative international classification, is in such a chaotic state that any serious attempt to bring order out of the confusion is to be welcomed. The recognition of the need of such classification is shown by the remarkable progress of what is known as the "International Classification of Diseases and Causes of Death," a manual of which will shortly be published by the U. S. Census Bureau. The present work, the first edition of which was published eight years ago, is primarily a guide for the clinical recorders in Bellevue Hospital in this city, but will serve as well in all other hospitals. This edition has been collated with the "International Classification" adopted in 1909. The orthography has been made to conform to that of the Basle Anatomical Nomenclature, but in the spelling of diseases it needs further revision in the matter of consistency. For example, it employs the ugly, if etymologically correct, term *leuchæmia*, but writes *lipæmia*, which consistently should be *liphæmia;* we find also *leucodermia* and *leukoma;* either the former should be *leukodermia* or the latter *leucoma;* according to the rules of etymology *leucodermia* and *leucoma* are the correct terms. In spite of these few inconsistencies and of the adherence to the nearly obsolete digraphs æ and œ, this list of diseases marks an advance toward a satisfactory nomenclature and is a work which will be of material assistance in the formation of an authoritative and definitive international classification of diseases.

A Text-Book of Medical Chemistry and Toxicology. By James W. Holland, A.M., M.D., Professor of Medical Chemistry and Toxicology and Dean Jefferson Medical College, Philadelphia. Fully Illustrated. Fifth Edition, Thoroughly Revised. Price $3.00. Philadelphia and London: W. W. Saunders Company, 1911.

That this work filled a want is obvious from the fact that it has gone through two editions in a comparatively short time. It is essentially a book for the medical student. As is pointed out in the preface, when a student is admitted to a medical college he is expected to have some knowledge of physics. Even when he has some knowledge of chemical matters having toxicological and therapeutical interest this needs to be refreshed and enlarged. But it not infrequently happens that beginners in medicine have not had adequate preparation in elementary chemistry. This being so, the ground must be prepared for the consideration of the practical application of physiological chemistry and toxicology by the elucidation of chemical philosophy. Hence this volume, which fulfills its stated object in an eminently satisfactory way. Indeed, it may be said that if the student masters the salient points of the book he will possess a sufficiently good working knowledge of medical chemistry and toxicology in so far as reading will help him. The illustrations are numerous and graphically interpret the text. The volume is well printed and in all respects may be recommended to medical students as a useful and comprehensive textbook.

Manual of the Diseases of the Eye. For Students and General Practitioners. By Charles H. May, M.D., Chief of Clinic and Instructor in Ophthalmology, College of Physicians and Surgeons, Medical Department, Columbia University, New York, 1890-1903; Attending Ophthalmic Surgeon to the Mt. Sinai Hospital, New York; Consulting Ophthalmologist to Bellevue Hospital, to the French Hospital, to the Red Cross Hospital, and to the Italian Hospital, New York. Seventh Edition, Revised. With 362 original illustrations, including 22 plates, with 62 colored figures. Price $2.00 net. New York: William Wood & Company, 1911.

In the seventh edition of this work a new chapter has been added on "The Ocular Manifestations of General Diseases." Paragraphs have been inserted on subjects such as Larange's Operation for Glaucoma, The Use of Salvarsan in Syphilitic Ocular Affections, Krönlein's Operation, etc. Like the previous editions of this work, this book will be found extremely useful to the general practitioner and student, as it presents the fundamentals of the diseases of the eye in a concise and comprehensive manner. As a typographical criticism we would note that two successive pages are numbered 78—the subject matter of only one page being included in the table of contents.

Die Syphilis im Lichte der modernen Forschung. Mit besonderer Berücksichtigung ihres Einflusses auf Geburtshülfe und Gynäkologie. Von Dr. Franz Weber, Assistent an der Kgl. Univ.-Frauenklinik und Privatdozent für Geburtshülfe und Gynäkologie an der Universtät in München. Mit 8 Abbildungen im Text. Berlin: Verlag von S. Karger, 1911.

So much history has been made in the last decade so far as our knowledge of syphilis is concerned that old textbooks treating of the disease have rapidly become antiquated. Moreover, it is not the symptomatology of the disease, but its diagnosis and treatment that are of the greatest interest now. It is this aspect of the disease that Dr. Weber covers in his book on syphilis. He gives a short review of our historical knowledge of the "great plague" and then informs the reader of the results of animal experiments which have contributed so much to our knowledge of its causation. The *Spirochæta pallida* is discussed in the next chapter, the technique of searching for it being fully given. Many pages are devoted to discussion of the Wassermann reaction, technique, modifications, specificity, and occurrence in various stages of syphilis being fully considered. This chapter is a valuable one for the busy doctor who has not had a chance to read many of the original papers on the subject. The rôle of syphilis in diseases of women and children—"syphilis of the innocent" and inherited taint of the disease—form the subject of the next chapters. The therapy, with some consideration of salvarsan, is the last subject considered. The book is not in any sense original, but it is one of the many useful compilations which appear so frequently in Germany. Its perusal should prove profitable to all physicians.

Diät und Küche. By Dr. Wilhelm Sternberg. Price $1.25. Würzburg: Verlag von Curt Kabitzsch, 1911.

In this monograph, "Diet and Kitchen," Sternberg lays stress on the importance of diet with regard to the different foods and also their preparation in the treatment of disease. He maintains that the new results obtained experimentally on animals with regard to diet cannot be taken over into human pathology. The taste of the civilized man cannot be compared with that of a dog.

Hygiène de l'Alimentation dans l'état de santé et de maladie. Par le Dr. J. Laumonier. Fourth Edition. Price 80 cents. Paris: Felix Alcan, 1911.

The present book of Laumonier contains a minute description of the diet in health and disease. The author lays much stress on the right preparation of foods. The culinary art is useful not only to increase the enjoyment of the meals in health, but also in disease. Laumonier's work deserves high commendation.

Die Pathologie und Therapie der Enteroptose. Von Dr. Walter Zweig. Price mark 1.50. Halle a. S.: Carl Marhold, 1911.

Zweig considers enteroptosis mostly as a congenital condition, agreeing in this with Stiller's views. Stiller believes that he found a definite diagnostic point of the asthenic habitus in a floating tenth rib. An entire literature has developed about the significance of this free tenth rib. About ten years ago the author wrote an article on this question, the conclusions of which he still adheres to. The prevailing number of persons suffering from a floating tenth rib are also afflicted with enteroptosis. There is, however, a considerable minority of cases in which we meet with a floating tenth rib without ptosis of the digestive organs, and, on the other hand, there are persons with purely organic troubles, without any nervous dyspeptic symptoms, that show a floating tenth rib. When enteroptosis is accompanied by constipation the latter cannot be looked upon as secondary to the former, but is caused by the general depression of the nervous system. Just as we find in the stomach disturbances of the motor functions caused by a disturbance of the vegetative nervous system, so the bowel also may be the seat of neuroses of a depressive or excitative character. We meet, therefore, frequently with constipation caused by a depression neurosis of the bowel or more rarely with diarrhea as the expression of an excitation neurosis. Neither condition has anything to do with the malposition, but is frequently encountered in enteroptosis associated with nervous dyspepsia. As to the operative treatment of enteroptosis the author thinks that, in view of the congenital nature of the relaxation of all the tissues, it is unlikely that an operative correction of the position of any organ will be of any permanent value. If we stitch up the kidney, stomach, or even colon, the symptom complex of the visceral neurosis will not be changed or improved in the least.

Diseases of the Stomach. By Charles D. Aaron, Sc.D., M.D. Price $4.75. Philadelphia and New York: Lea & Febiger, 1911.

The author has written a very practical and useful book on diseases of the stomach. Theoretical discussions have been briefly given where absolutely necessary. The indications for surgical intervention have been minutely described and the author takes rather a conservative view with regard to this new field. "Indiscriminate operation has done more harm to the advancement of gastric surgery than can well be realized. It is the internist who has to deal with the case after the surgeon has discharged the patient as cured. Some of these patients are sorry-looking individuals, and yet many an internist acquiesces without a word of condemnation of this sacrifice to experimentation. How absurd to accept unchallenged the assertion that most of the stomach cases coming into the hands of the internist are cases of incipient carcinoma and should be subjected to an exploratory operation! When surgical intervention is truly indicated there is no class of cases in which success is so gratifying; but, taken as a whole, less than 2 per cent. of stomach cases require surgery. The most frequent condition demanding surgery is obstruction of the pylorus, in which condition gastric retention is extreme. In severe cases food is found in the morning in the fasting stomach, often as much as three or four quarts, some of which was taken one or more days before. The stomach endeavors to compensate for the pyloric obstruction by increased muscular effort. This brings about hypertrophy of the organ, which is soon followed by dilatation. Dilatation is almost invariably present when there is stenosis of the pylorus."

Surgeons demand an exploratory laparotomy in every case in which the diagnosis is in the least doubtful and in cases which do not yield immediately to internal treatment. The number of cases which we should have to subject to laparotomy to no purpose would be very large were we to satisfy the demands of surgeons to perform an exploratory laparotomy in all doubtful cases. Moreover, this is much easier said than done. Patients complain of comparatively little trouble, which may be occasioned by an incipient carcinoma or equally as well by a neurosis, gastritis, erosion, ulcer, gastroptosis, cholelithiasis, or by disturbed gastric function originating in disorders of remote organs. When it is considered that two-thirds of all chronic diseases of the stomach belong to the type of neuroses or functional disorders, we can readily understand why the internist hesitates when the surgeon demands exploratory incision.

It must be admitted further that, while exploratory laparotomy is no longer a serious operation, it is not entirely free from danger. If we advise exploratory laparotomy when the manifestations of disease are slight the majority of patients will not submit, and if after such refusal a course of internal treatment is instituted and the patients recover we shall subject ourselves to many unjust reproaches. An important point to remember is that upon examining an opened stomach it may be very difficult for the surgeon to interpret correctly the traces of a possible old ulcer or other finding. What he may judge to be benign frequently proves to be malignant, and what seems to him malignant may be benign.

The author has brought the book up to the very last development in literature, giving the latest improvements and means of diagnosis and treatment, as the treatment of gastric ulcer by means of bacterial vaccines and duodenal alimentation, the bead test, mechanical dilatation of the pylorus, etc.

The book can be highly recommended to the general practitioner, who will find in it a most accurate and clear description of the present state of our knowledge of diagnosis and treatment of diseases of the stomach.

A System of Medicine by Many Writers. Edited by Sir Clifford Allbutt, K.C.B., M.A., M.D., LL.D., D.Sc., F.R.C.P., F.R.C., F.I.C., F.C.A., Regent Professor of Physic in the University of Cambridge, Fellow of Gonville and Caine College, and Humphry Davy Rolleston, M.A., M.D., F.R.C.P., Senior Physician St. George's Hospital, Physician to the Victoria Hospital for Children, sometime Fellow of St. John's College, Cambridge. Volume IX: Diseases of the Skin, General Index. Price $6.00. New York: The Macmillan Company, Limited, 1911.

This, the last, volume of the second edition of the System of Medicine deals with diseases of the skin. In the present edition of this work diseases of a special character are discussed separately. Perhaps few branches of medicine have exhibited more progress than that of diseases of the skin, old views during recent years having been continually giving way to more modern conceptions. Thus the editors have found it necessary not only to revise but practically to cause to be rewritten this part of the system. The writers of the various monographs are all British authorities, and indeed with but one exception attached to London hospitals. It goes without saying that there are few if any cities with a greater wealth of material, even so far as skin affections are concerned, than London, and the result of this volume shows that the authors have made good use of this material. One of the most prominent authorities on skin diseases, some of whose contributions are in this work, Dr. H. R. Crocker, died while it was in press, while the articles contributed to the first edition by the late Dr. J. F. Rayne have been rewritten for the most part by Dr. T. Colcott Fox, who has also provided a number of new articles. In discussing or reviewing a series of papers treating solely of skin diseases, so thoroughly and at such length as the papers contained in this book, one is confronted with an embarrassment of riches. An interesting fact is pointed out in the article on Lichen, written by H. G. Brooke and revised by I. M. H. MacLeod, that by a laborious process of elimination which it has taken a century to accomplish dermatologists have come to see that it is better to cease to apply the name "lichen" to an anomalous crowd of more or less papular affections and to restrict it to one specific form of disease, lichen planus, of which Hebra's lichen tuber is a rare and aberrant acute manifestation. One of the most notable examples of progress is that with regard to the fungi of so-called ringworm and favus, a subject discussed in a masterful way by Sir Malcolm Morris. Dr. G. W. Goodall has a very instructive and commendably brief paper on rashes due to the administration of animal sera. Concerning what is known as anaphylaxis Dr. Goodall confesses that the causes are very obscure and that the matter so far as explanation is concerned is still in the hypothetical stage. Mr. Jonathan Hutchinson, son of that great authority on syphilis, Sir Jonathan Hutchinson, writes a chapter on the eruptions of syphilis and states that the sheet anchor of treatment for these affections is the prolonged administration of mercury. Referring to "606" he says that the striking effects of hypodermic injection of dioxydiamidoarsenobenzol on the various cutaneous manifestations of syphilis are now accumulating. Dr. James Galloway contributes an instructive article on diseases of occupation and refers to the large number of cases of scabies and other contagious diseases which occur in individuals after a vacation and puts much of this down to crowded hotels and sleeping cars. The volume throughout is well written, the subjects are excellently arranged, the illustrations are good and sufficiently numerous to serve their purpose, and the last book of the second edition of Allbutt's System of Medicine is in keeping with the high standard maintained in all the former volumes. As a work of reference the second edition can be strongly recommended.

Society Reports.

MEDICAL SOCIETY OF THE STATE OF PENNSYLVANIA.

Sixty-first Annual Meeting at Harrisburg, September 25 to 28, 1911.

GENERAL SESSION.

Tuesday, September 26—First Day.

THE PRESIDENT, DR. JOHN B. DONALDSON, OF CANONSBURG, IN THE CHAIR.

The Care of Advanced Cases of Tuberculosis.—Dr. W. F. WILLCOX of Ithaca, N. Y., presented this communication in which he stated that the effective segregation of an increasing proportion of the advanced cases of pulmonary tuberculosis was attended by a decrease in the death rate from that disease, no matter what other influences, favorable or unfavorable, were present. The failure to segregate an increasing proportion of the advanced cases of pulmonary tuberculosis was attended by a stationary or increasing death rate from that disease, no matter what other influences, favorable or unfavorable, were present. The rate at which the segregation of tuberculous patients increased in any community uniformly agreed with the rate at which pulmonary tuberculosis decreased. If it were granted that the death rate from tuberculosis varied regularly with the effective segregation of advanced cases, it followed that in combating the disease the main effort of public health workers should be directed towards the extension of hospital accommodations for advanced cases and the increased segregation of such cases.

DR. W. C. WHITE of Pittsburgh said that there were certain peculiar features of advanced cases of tuberculosis which were often lost sight of and which it was essential to consider before any scheme for their care could be adopted. Advanced consumptives were sick, and provision had to be made for their continuous stay in bed with adequate nursing. Our ordinary institutions for the sick refused them, sanatoria for the tuberculous refused them, private practitioners wanted to get rid of them, and boarding houses and homes discharged them without compunction. Few of them could ever be put in such shape as to return to their former occupation, and many of them under the proper care lived for many years unable to work. Those cases were sources of infection if they were the least bit careless and submitted to the scrutiny and remarks of acquaintances, they were very apt to become careless. Advanced cases had in most countries the rights of citizenship and could and did refuse daily to accept the opportunity open to them for institutional care for even a few weeks or months, thus making the large institutions far from centers of population of much less value than they would otherwise be. While much evidence could be adduced to show that a marked reduction in mortality in tuberculosis was obtained without care of advanced cases, the efficient and practical care of advanced cases was one of the important elements, if not the most important element, in our endeavor to control this disease. All patients carried danger with them to be spread when their habits were careless and no provision could be perfect which neglected any single class. No single type of institution would handle all cases. No voluntary power could handle more than a small percentage of any class. The law must eventually be the means by which this infection would be controlled. He could but feel that the first move to secure the desired results in this work must be the return of the care of these cases to the general hospital. Only in this way could doctors and nurses be efficiently trained, and, furthermore, advanced cases of tuberculosis properly cared for as such would not subject other inmates of such hospital to anything like the danger to which they were now daily being subjected by inadvertently admitted advanced cases of tuberculosis because of some other disease with which they happened to be suffering. Proper provision should also be made for tuberculous cases in asylums, jails, poor houses, orphanages, homes, etc. A third necessity, and he considered this easily third in importance, was the provision of separate institutions for the care of advanced cases. Finally, proper provision must be made for the care of advanced cases in their homes.

DR. WILMER R. BATT of Harrisburg said he was unable to accept the conclusions of Professor Willcox because the statistics which he had submitted in regard to the reduction of mortality in England and other European countries referred to the general institutional care of tuberculosis and not to advanced cases alone; owing to the migratory tendencies of tuberculous sufferers the mortality rates in any single American city were not sufficient evidence upon which to base accurate estimates of the decline of the disease from any particular item of prevention; considering the average duration of tuberculosis it was impossible to estimate the value of preventive measures which had not yet reached their full development. To provide principally for advanced cases of tuberculosis and minimize the opportunity for those suffering from the disease in the early stages could be excused only on the assumption that it was the hopeless and dying cases that were dangerously infected. The bacilli of incipient or moderately advanced cases were as dangerously infective as those of advanced cases and infinitely more widely distributed.

DR. T. B. APPEL of Lancaster said that speaking from the point of view of the general practitioner the conclusions drawn by Professor Willcox seemed to him to be most timely and most important. As the terminal stages of tuberculosis seemed to present the greatest danger of contagion, more effectual precautions should be taken in such cases if we hoped to combat the spread of consumption. We as general practitioners knew that patients came back from sanatoria educated in the proper care of themselves, but they came back to the same unsanitary surroundings, and in his experience in time became careless, lost ground, and in the end succumbed to septic phthisis. Therefore, if better means of segregation of those poor, ignorant, hopeless cases could be obtained their care would be much more effectual.

DR. WILLCOX, in closing, said he had been specifically asked to speak on the care of advanced cases. It was natural therefore that he should say nothing on the care of early cases or upon any other topic besides that. It was possible, however, that in avoiding those topics that he might have laid himself open to a misinterpretation that he regarded the care of advanced cases as the only thing that should be done. He would not be so interpreted. The main factor in the decrease in death rate from tuberculosis had been and probably would continue to be the efficiency of segregation for advanced cases.

The Bearing of Pneumonia, Considered as a Secondary Malady, Upon Treatment.—Dr. H. A. HARE of Philadelphia called attention to a previous communication made by him a year ago on this subject in which he reported his experience as to the importance of studying the relative ratio of pulse rate and blood pressure in the course of croupous pneumonia, and expressed the belief that such observations were of the greatest value in the application of correct treatment. Since then increasing experience with this plan had served to convince him still more that it was practically an essential factor not only in treatment but in prognosis as well. The favorable ratio in croupous pneumonia was one in which the pulse rate per minute was less than the number of millimeters of mercury

as shown by the sphygmomanometer. In other words, if the pulse rate was 90 and the blood pressure 120 the patient was doing very well. If the pulse rate was 100 and the blood pressure 110 he was not doing as well as before. If the pulse rate was 110 and the pressure 110 something must be done to bring back the normal difference already referred to, and if the pulse rate was 120 and the pressure 110, the patient was in grave danger and would probably die unless very active treatment caused him to rally before this abnormal ratio had lasted for any length of time. The fall of pressure might be considered to be the result of the toxemia which directly affected the vasomotor centers of the walls of the vessels themselves, or it might be due to a direct effect on the heart muscle, whereby this organ was unable to pump strongly enough to maintain pressure. It was of some importance to determine, if possible, whether this fall of pressure was due to one cause or the other, for, if it was vasomotor, or vascular, direct cardiac stimulation was not needful, although it was true that most vascular stimulants were also stimulants to the heart. On the other hand, if the heart was at fault attention must be chiefly directed to the organ. If the vessels were at fault the difference between diastolic and systolic pressure would be marked, the heart, if strong, sending out a forcible wave of blood in an endeavor to fill the blood paths. If the pressure was low from a failing heart there would be little difference between diastolic and systolic pressure for obvious reasons. There was no treatment of pneumonia but there was treatment of the patient who had pneumonia, and this would vary in every case. Nor should any physician plume himself on great skill if his patient got well or go into the slough of despond if his patient died, if, on the one hand, a frank pneumococcic infection recovered or, on the other, an insidious infection caused death. It was only when recovery took place in the face of a small factor of safety that great credit was due the physician.

The Ehrlich Remedy in the Treatment of Syphilis.—Dr. Judson Daland of Philadelphia said that experience gained during the past 14 months made evident that salvarsan was not only an important and permanent addition to our means of combating syphilis, but in certain cases produced results most brillant and not otherwise attainable. The drug was now almost always given intravenously and complete sterility was absolutely necessary. Injection was best given in a hospital with the aid of two assistants and a nurse. All patients should remain in bed the first 24 hours after injection, and in case of syphilis of the nervous system or internal viscera the patient remained in his room in bed or in a chair the second day, and on the third day was permitted to move quietly about the hospital and afterward returned home but did no important work for four days. The hope of Professor Ehrlich that salvarsan would sterilize the syphilitic in one dose was no longer entertained, although this was possible in certain cases of primary syphilis. In most cases the dose should be repeated in one week. If the Wassermann reaction remained persistently negative for a period of three or three or more years the patient was viewed as free from disease, but, if it became strongly positive, other injections were given. Tertiary and congenital syphilis as well as syphilis of the nervous system required several injections and the patient should simultaneously receive the benefit of the mercury and the iodides. The contraindications to the use of salvarsan were advanced syphilitic myocarditis; advanced syphilitic disease of the aorta or coronary arteries or aneurysm; syphilitic aortic insufficiency; hemiplegia from ruptured syphilitic artery; advanced general paresis; advanced disseminated sclerosis; advanced tabes dorsalis; extreme debility or emaciation. A number of deaths had followed the administration of Ehrlich's remedy; it was therefore evident that in the long-standing cases of syphilis a thorough physical and general examination should be made before the injection was given. The indications for the use of the Ehrlich remedy in syphilis were: cases refractory to mercury, cases but partially improved by mercury, cases showing an idiosyncrasy to mercury, whereby therapeutically inefficient doses produced mercurialism; infective lesions occurring in prostitutes or the ignorant and careless.

The Care of the Insane.—Dr. T. H. Weisenburg of Philadelphia said that of all the problems which were now before the profession there was none more pertinent than the care of the insane. It seemed to the alienist almost nonsense that general hospitals throughout the state should take care of the medical and surgical cases and refuse to take care of the insane, thus making it necessary to send them to an asylum or a private sanatorium. The time had come when it was necessary that all general hospitals should have separate wards for the care of the member afflicted. A bill would be introduced in the next Legislature providing for the placing of all the insane of the state in state institutions with proper provision for the criminal insane, the feeble-minded and epileptic. In this way the care of the insane by the various counties will be abolished. There were to be established two laboratories for the study of the causes of insanity. A State Commission with an alienist of recognized ability at its head, to have absolute charge of all the State hospitals, was to be established. This bill should be actively supported by the members of the State Medical Society.

Wednesday, September 27—Second Day.

Lodge Practice.—Dr. Horace M. Alleman of Hanover asked whether there were any economic conditions justifying lodge practice, and said that in discussing this question the difference between legitimate contract practice and lodge practice should be remembered. The effect on the physician so engaged, he considered detrimental to good work and a hindrance to his advancement in his profession. He stated that the membership in these lodges was increased by openly advertising free medical treatment.

Dr. George E. Holtzapple of York believed that the question of checking this pernicious, evil, iniquitous practice would resolve itself into a personal effort on the part of every physician to help create and establish a proper sentiment against it.

Dr. Charles J. Cummings of Williamsport thought that the State Society should have a constitutional provision that no county society should be a component part of it unless said county society barred lodge practice.

Dr. Israel Cleaver of Reading remarked that until very recently he had thought that the Code of Ethics provided for that completely, but that he had found that it did not. He thought, however, that in the Berks County Society there was enough popular opinion to bar a man indulging in lodge practice from entering it. He suggested that the lodges should put the money paid by their members for medical advice into a fund from which to pay any physician that the member might choose to employ his regular fee.

Dr. Sterling D. Shimer of Easton said that in his County Society they had adopted a rule that no member should accept any contract work for less than his regular fee. His own contract work was paid in this way, though he got nothing extra for night calls.

Dr. Alleman, in closing the discussion, said that at Hanover there were two physicians doing lodge practice, one for the Moose, and one for the Elks. Both got their regular fees, but they accepted a forty per cent. reduction when they got their pay at the end of the quarter.

Need Business Qualities Interfere with the Successful Practice of Medicine?—Dr. Charles J. Cummings of Williamsport, in illustration of this point, cited the

careers of Dr. A. and Dr. B., located on opposite sides of the same street, who had begun life's battles on an equal footing. Dr. A., large-hearted, kindly natuured, over charitable, and easy in charges and collections, did not distinguish the sham from the genuine. Dr. B. possessed business tact. While appreciating true charity and responding thereto, he charged well for his services and was strenuous in his collections. The straw and chaff drifted to Dr. A.; the grain to Dr. B.

The Value of a Library to a County Medical Society.—Dr. James M. Anders of Philadelphia mentioned the importance of public libraries in American life, and emphasized the advantages of a medical library for each county medical society. He considered the working library a great factor in medical progress, and said that reference books and medical periodicals were indispensable to the young physician as a source of knowledge and inspiration. Dr. Anders stated his belief that the responsibility for the establishment of such libraries devolved upon the members of the county societies. He thought that a special committee of each society, cooperating with its secretary, who should also be the librarian, could raise a fund for the purpose with the aid of a small assessment. A part of this sum could be devoted to the purchase of new books, in order to keep the library up to date; but there would be many donations in response to an appeal for contributions of books and periodicals, as three-quarters of the books in existing libraries have been donated. In every county a suitable, centrally located room could be found, which could be readily reached by the members with the present means of transportation. The library might be made the meeting place of the society, so that reading matter might be returned and taken out at the time of the meeting.

Dr. Thomas A. James of Ashley stated that the Luzerne County Medical Society, which had started with a very small library, had over six thousand volumes, most of which had been given to it. Duplicates had been traded with other societies. Each member paid ten dollars a year, and a key was given him, admitting him to the library at any time, whether the librarian was there or not.

Dr. James Tyson of Philadelphia thought that the journals should be allowed to circulate by mail or otherwise from one member to another without obliging a man to go several miles to a center in order to return them.

Dr. John B. Carrell of Hatboro asked how a member in a remote corner of a county forty miles long and twenty miles wide could have access to a library situated at its center. He suggested having a library section of the society and requiring each man who wished to belong to it to contribute a certain amount of money.

Dr. Anders thought that all that would be necessary in order to commence such a library would be to set aside a small sum for the purchase of about a dozen books. Many other books and journals would soon be donated. He stated that many physicians in rural districts and the smaller towns did not publish rare cases that they came across for the reason that they were unfamiliar with the literature of the subject.

Municipal Milk Supply.—Dr. Ernest J. Lederle, Health Commissioner of New York City, stated in his paper that in New York they had come to believe that the only way to guarantee the safety of the milk supply was to require pasteurization of all but certain grades of high-priced milk. They had adopted a plan for the official grading of all milk into three classes, according to whether it was to be used for infants, for adults, or for cooking or manufacturing. A rigid inspection was established.

Milk and Its Relation to the Public Health.—Dr. Percival J. Eaton of Pittsburgh remarked that the public was being educated as to the value of good, wholesome milk, the experts' standards being constantly raised. He considered clean, raw milk to be better as a food than either pasteurized or sterilized milk, and said that when modified to suit the individual infant, it formed the best of the substitute foods. Because of the possibility of the infection of man by the bovine tubercle bacillus, tuberculosis among cattle should be eradicated. On account of its known rôle as a disease carrier, the production of all milk should be constantly watched by competent inspectors. Dr. Eaton further stated that the great value of milk depots was their relation to the morbidity and mortality of infants and young children. He made a plea for the more general recognition of the economic rights of the producer, and for the education of the masses to the belief that a good product deserved and should obtain a good price, the best being none too good for the children.

Dr. John B. Carrell of Hatboro said that it might as well be understood by the residents of cities that the price of such milk as was desirable, not only for infants, but also for adults, must be advanced; as it was an impossibility for the farmer to produce with profit the kind of milk that should be used unless the distributor and his profit were done away with. Dr. Carroll suggested that the municipality might attend to the distribution.

Dr. James M. Anders of Philadelphia did not believe that there would be a good milk supply until a prolonged campaign of education was carried on among the farmers and dairymen. He suggested a plant whereby milk could be produced with comparative cheapness, as follows: The farmer should take advantage of the Cow-Testing Associations in order to separate the profitable from the unprofitable cows and get rid of the latter, of which Dr. Anders stated most farmers carried a large percentage. He also considered it of importance for the farmers to learn the proper time and the best method for cooling the milk, as well as the best manner of straining it.

Dr. David P. Rettew of Coatesville believed in raising the price of milk, but not a great deal. He thought that one cent a quart added to the present price would make its production profitable. He doubted whether doing away with the distributor and putting the distribution in the hands of the municipality would work in certain cities, but he admitted that better business methods ought to be introduced in the distribution.

Dr. Henson F. Tomb of Johnstown stated that the farmers already had a good deal of education, and were not going to produce milk at the present price. They would sell their cows and take to raising hogs and horses. He thought it queer that the newspapers should say so little about the high price of butter or cheese, but should say so much about any proposal to increase the price of milk.

Dr. John C. DeVenney of Harrisburg stated that in Cumberland County cows that formerly cost but thirty dollars sold for seventy to ninety. The price of grain had also advanced, because the mills that formerly ground the grain in that county were idle, and it had to be transported. He had known of cows being killed for tuberculosis that really were suffering from having eaten nails with this grain. One cow had a nail in her lung.

Dr. Henry C. Westervelt of Pittsburgh said that milk had very materially improved in quality and cleanliness without any tremendous increase in its price. The farmer was not using more men, but making them do their work better. He believed in a campaign of enlightenment, but not that of the farmer or dairyman. He would enlighten the mothers, who would soon enlighten in turn the men who supplied the milk. In Pittsburgh the mothers could take samples of the milk to the municipal laboratory and get a report on it without the knowledge of the dealer.

Dr. Thomas Benton Hall of Waynesburg thought that the matter of cow-testing should be emphasized, and stated that the difference of two quarts of milk a day ex-

isting between a cow producing twenty-three and one producing twenty-five quarts was just the difference between a profitable and unprofitable cow.

Thursday, September 28—Third Day.

The Prescribing of Glasses by the Family Physician.—Dr. James Thorington of Philadelphia said that knowledge of optics together with a medical training were the prerequisites for those who would prescribe in any way for the eye. The time was opportune that at least one family physician for every 1000 of the population should devote at least part of his time to prescribing glasses. The people would much rather have their eyes cared for by physicians than go to the opticians, and one knew that the examination of the eyes and selection of glasses for them with or without the use of drugs was a part of the practice of medicine and it required the skill of one who was a graduate in medicine.

Dr. L. Webster Fox of Philadelphia emphasized the facts that it was important that medical students should be given instruction in refraction and that medical men were more capable of giving aid in cases of defective vision than were laymen. It was his conviction that the business of supplying the community with spectacles was of profound importance and that this business was shamelessly prostituted to money making. The optician should be placed upon precisely the same legal standing as a druggist.

Dr. W. W. Blair of Pittsburgh said that it had been argued that if all the work in refraction were to be handed over to the physician there would not be a sufficient number of physicians to do the work. This might have been true in the past, but the time was rapidly coming, now that courses in refraction have been introduced into our medical colleges, when more and more physicians will be doing refraction work.

Some Considerations of the Cancer Problem.—Dr. Christian B. Longenecker of Philadelphia said that the distinction between malignancy and non-malignancy could be made only by examining all suspected growths critically and impartially, confirming this by the microscope and regarding all suspicious enlargements as malignant until demonstrated to be otherwise. The physician seldom saw the patient in the early stage, therefore he was not in the majority of cases to blame for the failure of an early diagnosis. If there was any doubt as to malignancy the physician should snip off a portion of the growth under cocaine, being very particular to include a portion of the base and the limiting side wall and to submit it to a competent pathologist for an opinion. A differential diagnosis between cancer, tuberculosis, and syphilis was often very difficult without resort to a microscope. The diagnosis having once been made, early and radical operation was the only thing to be considered. If the patient absolutely refused the knife then cataphoresis, *x*-rays, radium, and carbonic acid snow, all of which had given good results in certain cases, might well be resorted to.

The Diagnosis of Carcinoma of the Stomach (Lantern and Cinematographic Demonstration of Peristaltic Movements).—Dr. George E. Pfahler of Philadelphia said that the importance of an early diagnosis of carcinoma of the stomach was recognized by all physicians since it was only in the cases diagnosed early that anything but temporary relief could be offered. The surgeon still advised exploratory operation, but patients frequently refused this operation until their symptoms became very serious or until too long a time had elapsed to offer them a cure. One could not say that such an operation was without danger, but an *x*-ray examination was accurate, painless, and harmless. At present very few cases presented themselves for examination until the disease was well advanced, but even in this late stage examination was valuable to determine the exact state of the disease. When a patient past 40 years of age had loss of appetite without any change of habits, distaste for meats, inability to digest solid foods, pain in the region of the stomach, he believed that a positive diagnosis could be made in nearly case in which an indurating carcinoma was present. In some cases in which good peristaltic waves were present a negative diagnosis could be made. Other physical and chemical examinations should not be neglected.

A New Sign in the Diagnosis and Treatment of Ulcer and Carcinoma of the Stomach.—Dr. Edwin Zugsmith of Pittsburgh read this paper, in which he said that a sign of gastric ulcer and carcinoma, which he believed had not heretofore been described, was an abnormal dulness to percussion in the second interspace extending for a variable distance on both sides of the sternum. In observations extending over a period of a year he had noted the presence of this sign in cases of gastric ulcer and much more positively in cases of gastric cancer. Unless the percussion stroke was very delicate the sign would not be found, for the dulness would be obscured by lung resonance. Upon the healing of the ulcer the dulness disappeared. As he had not been able to make any postmortem observations he was compelled to rely upon surmise in explaining the presence of this dulness, his conception being that it was directly due to enlargement of the lymphatic glands lying along the sternum.

(To be continued.)

MEDICAL SOCIETY OF THE STATE OF NEW YORK.

FIRST DISTRICT BRANCH.

Fifth Annual Meeting, Held at Yonkers, October 12, 1911.

(Special Report to the Medical Record.)

The President, Dr. W. S. Gleason of Newburgh, in the Chair.

State Movement for the Suppression of Tuberculosis.—The following resolutions endorsing the State movement for the suppression of tuberculosis now being carried on by the Charities Aid Association in cooperation with the State Department of Health were unanimously adopted.

Whereas: One-third of those who die between the ages of fifteen and fifty, at a time when they have assumed their greatest responsibility to society by becoming producers and supporters of familites, die of tuberculosis, a disease which is declared by scientists to be curable, preventable, and communicable, for the control of which hospital, dispensary, and public nursing provision is absolutely necessary, and

Whereas: It is a well-recognized duty of government to protect the people from communicable diseases, and seventeen counties in this State have either established or have voted to establish county hospitals, eight cities have established hospitals for the treatment of this disease, six cities have outdoor camps, twenty-five cities have free dispensaries, thirty-four cities have visiting nurses, nine cities have special relief agencies, and

Whereas: The New York State Grange, the Catholic Mutual Benefit Association, the Ladies' Catholic Benevolent Association, the Knights of Pythias, the State Workingmen's Federation, the State Railway Clerks' Association, and the County Medical Societies of thirty-two counties have given unqualified endorsement to the movement for the establishment of county hospitals for tuberculosis; therefore be it

Resolved: That the First District Branch of the Medical Society of the State of New York endorse the program for "No Uncared-for Tuberculosis in New York State in 1915," now being prosecuted in this commonwealth by the

State Charities Aid Association in cooperation with the State Department of Health, and that all county and local medical societies in the First District be requested to take similar action and to call upon the Board of Supervisors in their respective counties to furnish hospital provision for all classes of cases; and petition the Boards of Aldermen in their respective cities to provide facilities for free clinical diagnosis and for the instruction by nurses of the tuberculous sick in their homes; and be it further

Resolved: That the secretary of the First District Branch be instructed to send copies of these resolutions to all county and local medical societies affiliated in this district.

President's Address.—Dr. W. S. Gleason of Newburgh made an urgent plea for a larger attendance at the meetings of this branch of the State Society. He said that its membership was larger than that of the other district branches and they should not be satisfied with an average attendance. The need was not so much an increased membership as an awakening of the inactive members. The educational feature of the society was a strong one and could not be attained by a desultory attendance; they could not afford to slight this opportunity any more than they could hope for progress in their work and thought by slighting medical literature. The county societies should announce the branch meetings at least four months beforehand and should use every effort to bring out the members. The programs should be prepared long enough beforehand so that the members could know what features of interest there would be. They all had a responsibility, and by honestly and faithfully assuming it they could maintain a standard of excellence in their society work and arouse the dormant element into action.

Double Dislocation of the Hip—Exhibition of Patient.—Dr. A. E. Chase of Tarrytown said that double dislocations of the hip had been reported but thirty-nine times in one hundred years. Of those 39 cases 5 were indefinitely reported or merely mentioned. Therefore there were only 34 cases reported so far, and the case he wished to record and present made 35 cases that were definitely reported. So far the mortality had been 8 per cent. Of the causative factors a blow upon the lower part of the back by some heavy blunt instrument was usually the cause. Another cause might be a fall from a height with the legs wide apart. This usually resulted in a double obturator dislocation. But the usual cause was the heavy blow upon the back. There had been reported 6 cases of double iliac dislocation. The patient he presented was standing upon both feet, bending over, with his hands close to the ground. A steel beam weighing about 1,000 pounds struck him in the back on a line with the crest of the ilium. The shock was not great, and he did not lose consciousness. The double ischiatic dislocation was easily made out. The patient was shown two and a half weeks after the accident. He was a man, twenty-nine years old. His history was entirely negative. In none of the 35 cases reported was there any history of bone disease or any lesions of the hip joint. The patient presented was perfectly developed. This was the first case of double ischiatic dislocation of hip ever reported.

The Etiology of Arterial Sclerosis.—Dr. Henry Lyle Winter of Cornwall said that he presented this paper because in his work, that of a neurologist, there was no other one thing which presented itself for consideration so often as the condition of the arteries. As arterial sclerosis was due to causes acting in the blood current or on the arterial walls, etiological injury might be confined to those conditions which might exert an influence on these. Inherited tendencies to arterial sclerosis, to family presenility, and probably to the ordinary infections and autoinfections were due to the faulty functioning of some organ normally protecting metabolism through the blood current. The organ referred to meant the adrenals. It had been demonstrated that adrenal feeding would produce arterial sclerosis. If the adrenals were protective organs and if their activity was increased and disease was thereby produced which was due to the failure of their function, it was conceivable that with a blood pressure maintained at a point of harmony with metabolism the addition of a quantity of adrenalin sufficient to raise that blood pressure might so far disturb metabolism that toxins would be produced at an increased rate. If this toxin production were sufficient the effect would be the same as though the production were normal and the protective activity of the glands lowered. In considering the high blood-pressure present early in arterial sclerosis as due to the overactivity of the adrenals they must agree that overactivity of a functioning tissue could only be called for by the presence of an unusual task. The only thing which could call for an overactivity of the adrenals was the presence in increased quantities of those substances in the blood against which the gland afforded protection. The progress of arterial sclerosis was accompanied by progressive changes in the adrenals. Whatever part the adrenals might have played in the beginning was continued, but, as the disease progressed, became a secondary factor in the persisting high blood pressure. As long as the heart action continued forceful enough it was that organ in concert with the over-full arterioles which maintained the blood pressure. When the heart muscle began to fail blood pressure was lowered. This coincided with the findings of Mott, who reported atrophic adrenals in the late stages of arterial sclerosis. Had the adrenals remained active the blood pressure should have remained up. Dr. Winter called attention to the fact that in the final stages of arterial sclerosis toxemias were common, and it might not be straying far afield to connect these toxemias with the cessation of adrenal function, and also that he had often seen these advanced cases kept comfortable and perhaps alive for several years by regularly administered small doses of strychnine. While this drug was supposed to be contraindicated in arterial sclerosis it would be found to be of advantage in these terminal cases. The theory of the writer was that strychnine took the place of the missing adrenal action by maintaining the blood pressure, through the heart perhaps. He had tried out this theory by administering adrenal glands to two cases who had been on strychnia. In one case the results were satisfactory, while in the other there was an appreciable increase in blood pressure and the patient was uncomfortable. The author felt convinced that the adrenals were directly concerned in the pathological processes discussed, and further inquiry might prove that other ductless glands joined with them in affording protection to the circulation. Dr. Winters was of the opinion that the explanation of the etiology of arterial sclerosis could be reached only through these channels.

Dr. W. Travis Gibb of New York said that in his capacity as visiting surgeon to the Home of the Aged and Infirm (the old Almshouse), on the island, he saw many cases of arteriosclerosis. While he did not feel competent to discuss the disease along scientific lines, it had always interested him to note that those cases of arteriosclerosis that came under his care did so contrary to the cases seen in private practice. The people met with in private practice loved to live, to eat and drink, and do as they pleased, and they died comparatively early. Whereas in the city home they were on a strict diet (meals cost about 12½ cents a day) and these patients apparently never died; they lived indefinitely. Dr. Gibb had seen cases of arteriosclerosis in which the arteries were hard enough to break. This was a practical part of the subject, why did these paupers live so long? They must go to bed early because they have no light after

a certain hour. Why these paupers should live indefinitely while the patients seen in private practice died so early was an important question.

Dr. William Benham Snow of New York said that Dr. Gibb had touched upon an etiological factor of the greatest importance. It seemed to him that that one point in the family history had not been sufficiently emphasized by Dr. Winter, the habits of the family, especially the habits of gormandizing, overeating. Dr. Gibb had brought out a very important point in the treatment of these cases, the placing them under restraint. That was the custom of most of them who were handling such patients. To prolong the life of these patients attention should be paid to their food, to their exercise, and to the correction of any faulty conditions existing in the alimentary canal. Dr. Snow was much interested in Dr. Winter's delineation of the relation of the adrenals to this disease and he fully agreed with what he had stated. These patients with arteriosclerosis could be made more comfortable by lowering the blood pressure and correcting the diet and habits of the individuals. Remarkable results followed the regulation of the diet and an occasional treatment with the high frequency current, say, once in two weeks.

Dr. Winter said he was as interested as anyone in having his patients live; if they did not live, how could he? With regard to the habits of the patient, that was just what he wanted to get away from, because two individuals with the same habits differed so; one would develop arteriosclerosis, the other would not. They had worked the tobacco, the alcohol, and the overeating causes until now there was nothing to do any more. There was some reason why alcohol would break down one man and not another; there was some weakness in the defenses. He believed that it was the activity of the adrenal glands that acted by way of protection. In the later stages of arteriosclerosis it had been his experience that the blood pressure was apt to be low. They knew that the condition of the arteries had little to do with maintaining the blood pressure; it was the condition of the heart; when this organ began to flag and tire strychnine was valuable because it acted through the vasomotor system, as did the high frequency current. The blood pressure was maintained in this way. Whether adrenalin acted that way or not Dr. Winter did not know.

The Present Status of our Knowledge of Poliomyelitis.—Dr. Simon Flexner of New York said that the State of New York had suffered severely from this new disease. The disease was so severe, and all concerning it was so mysterious in its aspects, that it was highly important that as much attention as possible should be given it. There were two ways to approach the consideration of this disease; first, the way it appeared among human beings and, secondly, the way it developed in the laboratory where it was produced experimentally. It was a remarkable circumstance that the human disease had in a short time come to be illuminated through the laboratory work concerned with the experimental production of it in animals and their study. As a rule the process was reversed. They knew the human disease. Then they tried to get light upon the human disease here and there by recourse to animals. In those cases the human disease was obscured until it was transmitted to animals. Then as point after point concerning the pathology was worked out in animals, they were able to correlate facts with the instances observed in human beings and their attention was directed to certain features of the disease which might occur and which actually were found to exist. It seemed to Dr. Flexner that a question of chief moment was this: What was the nature of the prevalence of the disease? What were its features as compared clinically either recognizable as poliomyelitis, or probably being examples of poliomyelitis, but with the absence of the characteristic signs of the disease and which might not early be determined to be due to the disease? There was no longer any discussion as to whether the disease was infectious or not; there was, however, a discussion as to whether it was contagious or not. If the disease was contagious, what was the manner in which the contagion was transmitted? Having determined that point, what were the means to be employed to limit the spread of the disease? The consideration of this question was a most important one because, evidently, as they were all aware, there was no remedy for the disease in the real sense. They could do nothing to arrest its progress once the disease was started. Evidently it was a disease that did not have a very high mortality, although the mortality was considerable. Fortunately, furthermore, it was a disease which had a tendency toward spontaneous recovery. The question of the prevention of poliomyelitis was closely associated with the nature of the cause and the manner of the distribution of the cause. Since there was no specific means of attacking the disease once it had shown itself, attention should be directed toward its prevention. The disease was a very characteristic one once it was fully developed; it expressed itself by paralysis of the motor system, but it was a mistake to suppose that the lesions were confined to the motor system, for the sensory system was also involved. Many physicians had been impressed with the amount of pain attending it. The reason that pain was not more frequently observed and did not appear more intense was because the motor effects of the disease obscured the sensory ones. It was commonly supposed that this disease was one that affected chiefly the nerve cells in the anterior nerve horns in the cord and spoken of as anterior poliomyelitis. As a matter of fact the disease was never confined to the anterior horn of the spinal cord; it always affected to a certain extent the posterior horn. Very often there were lesions in the white matter of the cord and very frequently there were lesions which extended throughout the length of the cord, involving the bulb and often the brain. It was a diffuse pathological process affecting the entire central nervous system. Sometimes they found foci here and there. But in a study of the disease in those cases that came to autopsy practically always there were found lesions more extensive than were supposed from a study of the effects of the disease, that was, the motor paralysis. Therefore, it was not a systemic disease; it was due to a poison that picked out certain specified portions of the central nervous system upon which to exert its activities. As a matter of fact the pathology of the disease indicated that the chief effects were exerted primarily not upon the nerve cells but upon the meninges and those parts of the meninges which followed the blood-vessels into the spinal cord and affected portions of the brain. The lesions there developed considerably before paralysis appeared at all and there was reason to believe that the disease might be confined to the meninges and prolongations of the meninges following the vessels into the spinal cord and affecting portions of the brain. In those cases the nerve cells were little or not at all injured. The disease would run its course without producing obvious, or any, paralysis whatever. It would be an accident if such cases were diagnosed as epidemic poliomyelitis at all. It was because there were these cases without the paralysis that the distribution of the disease was often difficult to determine. It was also for that reason that the connection between cases of frank paralysis and those that were not frank paralysis, or no paralysis, was difficult to determine. Therefore, when the statement was made that isolated instances of epidemic poliomyelitis had appeared in a community, it was subject to doubt whether they had not arisen or prevailed at the same time that other cases of the same disease which had not gone on to paralysis, and which had not been recognized

because the signs were so indefinite, but which might be still centers of distribution of the paralytic cases. Dr. Flexner wished particularly to emphasize the fact that there might exist a large number of these cases which did not terminate in paralysis at all. At present it was the custom to speak of them as examples of the abortive type of the disease. One could surmise what would happen if they accepted the contagious character of the disease. For example, if the so-called abortive type appeared and was not recognized a patient was allowed to mingle in the community, after which examples of the paralytic disease would appear, and no efforts would be made to trace them. He thought they could accept as established the existence of unmarked so-called abortive examples of this infection. Just as they came to learn in the distribution of measles, scarlet fever, diphtheria, and, generally speaking, the highly contagious diseases, the danger was greatest from the unrecognized examples. Therefore, the effort at prevention, the stamping out of the disease, must to a large extent be directed toward a better recognition of these unstriking examples of the affection which should be dealt with in the most effective manner possible. The particular cause of the disease was known, as well as anything could be known that you could not see. It was a microorganism. It could be handled with ease and with precision. It was so exceedingly small that not only had it not been seen but the probabilities were that with their present optical apparatus it is incapable of ever being seen. The evidence was that there was a particular germ that caused this disease. It was conceivable that some apparatus might be constructed which would enable them to see these exceedingly microscopic forms of germs. But it was only indirectly by means of magnification or some photographic methods that they could be brought to a size to affect the human retina. They were now in a position to say that any person who recovered from the disease, as animals who recovered from the experimeneal disease, developed a high degree of immunity to the germ which produced it. This immunity was associated with the appearance in the blood of the patient or animal of definite principles which had the power of destroying the activity of the virus of the disease. That fact made it possible to determine with accuracy whether the person had or had not passed through an attack of the disease. There was no difficulty in identifying the disease when it was frankly marked; the difficulty was in discovering the nature of the disease when it was not frankly marked. If the blood of a person who had passed through an indefinite attack of illness was mixed with the virus of the disease obtained from a human being who had succumbed to it and the two were allowed to remain together for a few hours and then inoculation practised, if the disease had occurred in this individual there would be no effect of the inoculation. This test was unmistakable. One could tell unmistakably whether this disease had existed or had not existed. This fact made it possible in doubtful instances to determine whether the disease had actually existed or not. The contagious character of poliomyelitis was one which had been a field for much dispute. That the disease could spread there was no doubt; the disease had arisen from previous sources of infection. The mystery simply involved the difficulty of determining whether a previous case or cases existed from which the infection arose. In order to explain that particular feature of the disease, a number of different hypotheses had been advanced. First, the disease was, strictly speaking, an animal disease and human beings only occasionally were infected from such a source. They frequently observed that domestic animals were subject to paralytic diseases, but it had not been possible to correlate the paralytic disease of the lower animals and the paralytic disease occurring in man and which was considered to be epidemic poliomyelitis. The other hypothesis attempted to explain the irregular distribution of the disease as possibly due to an insect carrier of infection. This would be a satisfactory solution if it could once be proven that insects actually carried the disease. It had been proven experimentally that the contamination of the insect made it possible for the virus to be carried a considerable distance. They survived forty-eight hours or longer, and they could survive in the viscera. This, however, was only laboratory experimentation. The point was significant. If one studied the manner of the distribution of the disease it would be found that it always followed the lines of human travel. The disease went from village to village, from place to place, from country to country, along the lines of human intercourse. There was something about the cause of the disease that attached itself closely to the human agencies. Insects which infested human beings could explain that if they could be shown to be the actual carriers of the disease. But in the absence of that, attention should be focused upon the possibility of human beings themselves being directly the carriers of it. There were certain facts concerning the pathology as studied in animals and found to be true in human beings that supported the belief that human beings themselves were the active carriers. If one inoculated the brain of a monkey the virus would be found to pass from the brain along the filaments of the olfactory nerve through the cribriform plate of the ethmoid plate into the nasal mucosa. It could be found in the nasal mucosa not only during the acute disease but afterwards; it was also found in the mucosa lining the pharynx, the larynx, the buccal cavity, and in the nose generally. Therefore, there was at least the possibility of a direct communication between the cerebrospinal membrane and the nasal mucosa through the perineural lymphatics. If this could be proven to be true perhaps there would be an infection of the secretions of the nose and mouth and these secretions could readily gain access to the external parts of the body and so serve to infect others. In the fatal cases studied last summer it was possible to find the germs of the disease in the mucous membrane of the nose and throat. The secretions in fatal cases examined were never free from them. The virus had a very high degree of resistance, especially when dried in secretions such as mucus. This explained why they could survive many days. Dr. Flexner believed, therefore, that at present the indications were that the human agency itself was the chief one to be viewed as responsible for the transmission of the infection. Clinical evidence had shown, furthermore, that not only a sick person with an abortive attack of the disease could transmit the disease but also a healthy person who had come in contact with an infected person might become its carrier. It was extraordinary that in a disease in which the contagion was so difficult to follow the secondary carrier, a healthy human being who had come into contact with the disease, was as much a source of contagion as one exposed to measles, scarlet fever, etc. The literature was unmistakable on that fact. The virus was capable of surviving outside the body much longer in the dried condition. Dr. Flexner said that what he had offered them was given with confidence and he wished to emphasize the fact that they must endeavor to control a disease of such a highly serious character: it had a fatality of 10 or more per cent. and crippled 75 per cent. of those infected. Quarantine measures that limited the spread to a certain extent, perhaps to a large extent, were possible and limited the spread of the disease through direct human agencies. In any community in which poliomyelitis appeared, in which also at about the same time there were appearing either in members of the same families cases of frank paralysis or other forms of the disease, especially in children, the indefinite febrile character not easily or at all readily correlated with the known forms of febrile

disease, suspicion should be aroused that it might be a case of abortive poliomyelitis and action should be taken to deal with such cases by some effective method of isolation and quarantine for the protection of the community.

Dr. Wisner R. Townsend said that all recognized the work that Dr. Flexner had done in teaching them the nature of the disease, but more should be done in teaching them how to prevent it, and what were the proper quarantine measures to take. What had interested him most since the epidemic of 1907 was the prevention of the deformities. The general mass of the profession should realize that in many of these cases the paralytic symptoms appeared late in the disease. He recently saw a child who preferred to lie on his stomach. Poliomyelitis was not suspected. The reason for this was that the back muscles were weak and this position afforded a gratifying state of tonus. He eventually made a good recovery. The large part of the work of the orthopedic surgeon was in correcting the deformities which were allowed to occur. They knew that if the muscles on the fore part of the foot became paralyzed the muscles on the posterior aspect would contract and cause an equinus, etc. These feet should be put up in braces early. Some men, however, did not advocate this. It was certainly gratifying to see a number of cases of beginning deformity that to-day had no deformity. He could show a number of patients who earlier could not walk, braces were applied, and to-day they walked well, some with and some without help.

Dr. H. L. Winter of Cornwall said that the abortive type was of interest clinically. They had a disease which they frequently saw referred to as a meningomyelitis. During the epidemics of poliomyelitis seen during the last few years he saw a number of cases where the meningeal symptoms, especially pain, were the only ones that indicated an involvement of the nervous system. Sometimes these cases went on to paralysis. Some would get well. This indicated a general pathological invasion rather than what was usually considered the pathology of poliomyelitis with confinement to the anterior horn cells. In reference to the mortality which had occurred in these cases which did not develop paralytic conditions, he said he had seen two or three cases which developed pneumonia, for example, and associated with the pneumonia more or less pain was referable to the spine and the extremities; in these patients death ensued but without sufficient pneumonic process to account for them. This led him to believe that death might be due to a general involvement of the meninges and spinal cord. With regard to the deformities, he thought it was the custom to put a time limit on the treatment, or a time when the treatment would be beneficial in paralytic conditions following an anterior poliomyelitis. So long as there was an electrical response in the disease when seen late, and the reaction of degeneration was not specially marked in those muscles, there would be hope for improvement by the electrical treatment. He had seen a number of cases given up too early by general practitioners and when the electrical treatment was followed out systematically, even after the lapse of two or three years, there would result an improvement. A great many of these cases could be kept out of the hands of the orthopedist if the general practitioner kept up the electrical treatment long enough.

Dr. William Benham Snow of New York asked whether the disease was confined to the meninges, producing paralysis by pressure, or whether in cases of paralysis it always extended into the cord. This he believed to be an important question. They should endeavor to keep these patients from the surgeon's hands. In the early cases that had come under his observation he had seen uniformly most excellent results. Here was one of the dangers of quarantine; they did not receive the treatment they should have if they were quarantined. The static machine was a bulky apparatus to take to the home of a patient, yet there was no treatment so effective as this. It was very energetic in relieving pressure and the metabolic conditions following the lesions. He had seen cases as late as the seventh or tenth week make almost complete recoveries following this treatment in his hands. The effect of this current was far more energetic than most had any idea of. It was due to the incoming and outgoing electrons. The best results were seen in the early cases.

Dr. Flexner said that the cerebral lesions were usually exhibited by paralysis of the face muscles and this might be considered precisely analogous to those cases in which the spinal cord lesion affected the spinal muscles. That was a perfectly definite and unmistakable group which had now come to be recognized. Many cases were recognized simply as meningitis; many went through their entire course as cases of meningitis only. These should be recognized readily but were differentiated with difficulty from other forms of meningitis. The only means of differentiation was in the fact that they sometimes got well spontaneously, or by means of lumbar puncture and noting the characteristic changes which always occurred in the cerebrospinal fluid. The use of the lumbar puncture was a means of determining in a large percentage of the cases (almost 100 per cent.) whether or not the disease was or was not poliomyelitis. Lumbar puncture was an operation that was not carried out by every physician, nor should it be. But if lumbar puncture was performed in doubtful cases, the question could be decided in all instances for or against poliomyelitis, because in all instances, whether associated with paresis or not, with meningeal symptoms or not, if the case was one of poliomyelitis certain characteristic changes would be found in the fluid, such as an increase in the number of cells, chiefly in the lymphocytes and protein matter. That was the only method available at present by which a certain diagnosis could be arrived at in the absence of definite symptoms. This was essentially a laboratory test, and was used to establish beyond peradventure the cases of this disease. The general practitioner was in a hard way to differentiate between the typical and the abortive types of the disease. The community should have the benefit of any doubt; if there appeared a suspicious case, one with an indefinite symptomatology, it should be at once quarantined. There was another fact concerning the disease which might be misleading; at the onset the paralysis might be very extensive and at the termination there might be little or none at all. About 25 per cent. he believed, judging from the statistics, of the paralyzed cases which survived would come out of the disease at the end of two or three years without any paralysis at all. There were a few cases which at the onset of the disease did not have much more paralysis than at the end of one, two, or three months. The disease was a communicable one, and how long to hold these patients in quarantine they did not know. He said there was good reason to believe that, under ordinary conditions, a quarantine period of four weeks was long enough. He was referring to those cases which ran an ordinary course with but a few days of fever. They had learned that the nasopharynx was a dangerous place from animal experimentation; in animals it was rare that one could find any virus in the nasopharynx at the end of three weeks. They had found, however, that the virus would remain there longer in some cases, and it meant this—in a period of three weeks the infection would clear up in all but a small per cent. In this small per cent. carriers of the disease would be produced. They had all kinds of carriers now, such as the typhoid carrier. The social conditions of to-day were such that they could not legislate against everybody. Therefore Dr. Flexner suggested that four weeks be the period of quarantine except

in those cases in which the febrile course had been prolonged, when there should be a corresponding prolongation of the quarantine.

Lactic Acid Cultures—Some Clinical Observations.—Dr. E. T. Harrington of Yonkers read this paper, in which he recorded the results of his observation on the use of lactic acid cultures in different forms of intestinal disease. For babies he had employed three or four teaspoonfuls daily and for adults three or four teaspoonfuls two or three times daily, depending upon the severity of the case. The writer subdivided that form of indigestion known as the putrefactive into two classes. The first class were the very marked putrefactive type with odorous stools and indican in the urine. In this class of cases indolactic acid would be absent, or present in small amount. This form of infection showed the presence of various anaërobic bacilli, most of which required an alkaline medium for active growth. In this form of indigestion the use of the lactic acid cultures was most effective and, in the author's experience, almost always curative. The diet in these cases was a most important factor. It should be low in proteids and high in carbohydrates. The second class of cases were those in which the colon bacilli and those of allied type were predominant. Here the urine showed indolactic acid, but seldom indican, and the stools were inoffensive. The treatment of this class of cases with the lactic cultures had not given results so radical and effective as in the former class. The diet was similar except that the sugars and sweet fruits were limited. The cases treated were mostly of these two types. In an experience of three years the writer had found that the lactic cultures would almost invariably cure the enterocolitis of infants. The cultures could not, of course, be expected to save a child who was within twenty-four hours of death when they were administered, because they were slow in their action, taking from two to three days before the stools became normal and the other symptoms subsided. No other medication was employed except lime water or a little calcium carbonate. The best diet during the administration of the cultures was whey or pure milk, but not milk containing preservatives as the cultures were prevented from growing by the preservative. For the first day or two barley water or other cereal water with lime water and milk sugar was given, and as the patient improved condensed milk was added. A peptone or hydrated albumin must be present with the sugar in order to produce a good growth of the bacilli. In administering this remedy they should remember that they were giving a thing of life and it was absolutely essential that it should be viable and capable of reproduction in a favorable medium.

Dr. Henry Moffat of Yonkers emphasized the importance of using the live cultures, especially in those cases in which the use of the dried tablets failed to produce the desired results. If one met with disappointing results in the use of the dried tablets in cases of intestinal indigestion, and especially in enterocolitis occurring in infants, one should turn to the live cultures made by some competent person in some laboratory and often surprising results would follow. The rapidity with which the green stools in cases of enterocolitis in a child changed to the normal color under the use of the live culture was encouraging.

Dr. George Swan Mooney of Yonkers said that in those instances in which there was a very disagreeable odor the use of the live culture caused it to clear up within twenty-four to thirty-six hours. He had not had the success, however, that Dr. Moffat had in stopping the green passages so quickly; this change did occur in from three to four days. While a great deal of credit was due to the use of the live cultures the regulation of the diet was a very important factor in the treatment of the enteric diseases, especially in children.

Dr. W. Stanton Gleason of Newburgh said he had become convinced that in ileocolitis by the use of the *Bacillus bulgaricus*, as outlined by Metchnikoff, and under whose guidance they followed out the line of treatment, they did get splendid results. However, no individual should allow his judgment to be guided too strongly in the consideration of something that was new. The adjustment of the feeding, the surroundings, and the change of air and other things would work out fully as much as would treatment by pure cultures of the lactic acid bacilli. But where one was obliged to keep the patient under the same environment, where he could not get the change of air, etc., the use of the pure cultures would be productive of the best results. In the fermentation in typhoid fever the defensive barriers were down; the system was relaxed, and the intestinal tract was filled with germs of the putrefactive type. These germs should be combated by something introduced into the intestinal tract to combat the putrefactive germs. In his experiments, carried out some nine years ago, he found that when the lactic acid bacilli were used there was no tympanic distension, the odor of the stools was never offensive, and the general course of the disease from the beginning was modified. This he believed was due to the lessening of the absorption of the toxins from the fermentative conditions which were present in typhoid fever.

Dr. Harrington said he had treated several cases of typhoid fever with the fresh cultures and his results had been more favorable than they had been hithertofore.

The Cesarean Operation.—Dr. J. W. Poucher of Poughkeepsie read this paper. He stated that the conditions requiring this operation and the safety attending it made it no longer the last resort of the obstetrician, but one that the experienced accoucheur should consider early. Cesarean section must be considered in cases of deformed or contracted pelves or where the outlet was occluded by exostosis, tumor, malignant growth, or where there was an outlet of less than 8 or 8½ cm. Craniotomy was justifiable only when there was positive evidence that the child was dead and that there was a pelvic diameter of three inches or more. Dr. Norris formulated the rule that when the true conjugate was less than 7½ cm. in simple flat, and 8 cm. in generally contracted pelves, cesarean section at or before the onset of labor should be the elective operation. At the beginning of labor cesarean section was an easy and practically safe procedure, but where all other methods of delivery had failed and where sepsis had very likely already taken place and the mother was in an exhausted condition the result was very doubtful by any method that might be chosen. The physician should know at least three months before confinement whether he had a normal pelvis or whether any condition existed that might complicate labor. When called to a case of labor he should prepare himself aseptically as though preparing to perform a laparotomy. Dr. Poucher reported six cases and described his operation, which was the one known as the high cesarean operation, where the incision was made from the umbilicus upward and downward. The incision was usually about six inches in length and the distance above and below the umbilicus was regulated so as to bring the opening well up over the fundus. He had not found the use of a rubber band slipped over the uterus to control hemorrhage necessary. He had also found that the fear of cutting the placenta was unfounded, as that accident had happened to him in his first operation and the bleeding had not been as free as one would have expected. None of Dr. Poucher's patients had suffered from surgical shock and convalescence was less eventful than in ordinary abdominal operations. He had never used undue haste and none of his operations had taken over half an hour. The advantages of the high incision were that it gave the best access to the cavity of the

uterus, that it was through a part of the uterine wall that would be less likely to subsequent rupture, and that it was through a part of the uterus furthest from large branches of the uterine arteries. There was at present a trend of opinion against the sterilization of women on whom this operation had been necessary, and there were on record a number of instances where a second and even a third cesarean section had been performed. In the six cases reported there was a mortality of 33⅓ per cent., but one was due to outside manipulation and the other to eclampsia, both having been operated upon as a last resort.

Dr. James E. Sadlier of Poughkeepsie, referring to those cases of contracted pelvis where the conjugata vera was shortened, said that it was very necessary that this class of cases should be determined beforehand. He was afraid that in these cases they had never considered the life of the unborn child, nor had they taken into consideration the morbidity of the mother or child following certain obstetric operations. He referred to the statistics read by Dr. Porter of Ft. Wayne, Ind., before the Southern Surgical Society two years ago. He reported 126 elective cesarean sections with a maternal mortality of 1.58 per cent. and a fetal mortality of zero; a maternal morbidity of 12.69 per cent. and a fetal morbidity of zero. From another source he collected a set of statistics of the same type in which obstetric operations had been performed. He found a maternal mortality of 1.14 per cent. and fetal mortality of 17.3 per cent.; a maternal morbidity of 42 per cent. and a fetal morbidity of 12 per cent. These figures spoke for themselves. The gynecological wards in hospitals throughout the country were filled with cases demanding operation of an obstetrical nature and they were left perhaps with a live patient but with a morbidity that was something terrific. They should stop and think over these cases which involved so much mortality and morbidity; would it not be better to do an elective cesarean section at the proper time and before the woman became infected? It was not alone the question of saving a life, but the question of the subsequent life of the patient. It was not so much the question of the childless mother or the motherless child; it was the question of invalid mothers and idiotic and epileptic children.

Danger Signals in Gynecology.—Dr. W. Travis Gibb of New York presented this paper. He stated that the actual number of gynecological danger signals was not very great, nor did they always point unerringly to the exact condition present; frequently they were dim, partially obscured, or irregularly combined, making a correct interpretation difficult, but they served the same purpose as the red lights along the railroad track, to draw the attention of the patient or physician to some impending or existing trouble, and were fulfilling the purpose for which danger signals were designed. Dr. Gibb cited a number of instances illustrating how ignorant was the average woman of the functions and anatomical conformation of her genital organs and how seemingly indifferent she was to conditions that were apparently intolerable when these organs were involved. A pimple the size of a pinhead on her nose would cause her the greatest anxiety, but a malignant growth on her vulva would often be ignored until it was too late. If women were ignorant of, or indifferent to, such obvious genital abnormalities as complete procidentia and external cancer, as the example cited showed they were in certain instances, it was not surprising to find them ignorant of many of the ordinary symptoms of gynecological diseases and indifferent for an indefinite time to a train of symptoms which ought to have compelled them to consult a doctor long before they considered such a step necessary. One of the most important gynecological danger signals was some interference with the normal periodic uterine hemorrhage known as menstruation. It was surprising how little the average woman knew about this important function. Normally the menstrual flow occurred at regular intervals of about twenty-eight days, lasting from three to five days, produced a loss of blood of from six to eight ounces, and was accompanied by slight discomfort to the individual. Any marked departure from this standard and all loss of blood not in relation to this period should be considered abnormal and in the majority of cases should be regarded as a danger signal by the patient or her physician. The absolute absence of this periodical bleeding during the period when menstruation was to be expected, except for the physiological cause of pregnancy or lactation, was abnormal and frequently a danger signal of great importance, for it might mean the absence or complete atrophy of one or more of the internal genital organs connected with the function, atresia of the uterus or vagina, chronic metritis or endometritis, the presence of some nervous disease, or of some organic or general disease as tuberculosis, syphilis, cancerous cachexia, leukemia, or nephritis. It was frequently one of the first indications of a general infective disease such as myxedema, diabetes, acromegaly, exophthalmic goiter, Addison's disease, or chlorosis. The administration of large doses of morphine, opium, mercury, acetphenetidin, alcohol, arsenic, and phosphorus might produce the same results. Excessive bleeding, whether at the menstrual period or during the intermenstrual period, might be regarded as a danger signal of the greatest import, for such irregularities might be symptomatic of subinvolution, incomplete abortion, ectopic gestation, submucous fibroids, malignant disease of the uterus and its contents, hydatid mole, hemophilia, purpura, or some specific infective disease, any of which left unrecognized and untreated would eventually result in disaster. Excessively painful menstruation might be regarded as a danger signal due to cervical and uterine stenosis, uterine flexion, obstruction by fibroids, salpingitis, ovaritis, uterine hyperemia, imperfectly developed uterus, endometritis, and neurasthenia. Post-climacteric hemorrhage was a danger signal of particular significance and demanded immediate and careful investigation. Unfortunately, it was the popular impression among women that increased and irregular bleeding was a necessary accompaniment of "change of life" or menopause. One of the most serious gynecological conditions which displayed few but very characteristic danger signals which were too frequently disregarded by the patient and often overlooked by her family doctor was ectopic gestation. The frequency with which these cases were seen by the gynecologist too late for successful operative interference ought to emphasize the fact that the danger signals of this serious condition were not sufficiently well understood to be readily recognized. The gynecological danger signal most frequently encountered was vaginal discharge or leucorrhea. Not that all leucorrheas were indicative of serious gynecological lesions, but all discharges from the female genital organs should be regarded with suspicion until it was proven by physical and microscopical examination that they were benign. When it was known that a discharge not necessarily profuse, offensive, or painful accompanied such diseases as gonorrhea, malignant disease of the genital tract, uterine fibromata, decomposing material in the uterus, endometritis, metritis, pyosalpinx, and a dozen other serious conditions, the necessity for the careful determination of the origin of the discharge was apparent. Dr. Gibb said that in his work as surgeon to the New York Society for the Prevention of Cruelty to Children he had examined 1,500 girls under the age of sixteen years upon whom it was alleged the crime of rape had been committed. Of this number about 12 per cent. had some form of venereal disease and 90 per cent. of this disease was gonorrhea. Many of these infections were no doubt due to the superstition that obstinate venereal disease would be cured by

intercourse with a virgin. It was their routine practice in these cases in which leucorrhea existed to make a microscopical examination. The presence of gonorrhea in a child, however young, was as much a real danger as in an adult. Among the gynecological danger signals displayed as the result of physical examination were loss of normal motility; points of excessive tenderness; irregularities in contour, size, and texture of the cervix; while an enlargement of the body of the uterus, if not due to pregnancy, might be caused by fibroid, cancer, or retained menstrual fluid. Any laceration of the cervix might well be regarded as a danger signal. Lesions of the external genitals indicative of danger to the patient's life or health might be the result of tuberculosis, gonorrhea, syphilis, malignance, or elephantiasis. The presence of any of these danger signals ought to be the indication for making an exhaustive examination in the effort to make an early diagnosis.

Some Modern Surgical Principles in the Treatment of Surface Wounds.—Dr. E. C. Thompson of Newburgh presented this paper. He said that he would offer no apology for a presentation of fundamental principles; such apology should come from the medical schools, where too often the curriculum was more suited to post-graduate work than to the preparation of the general practitioner. The tendency had been toward a more rational treatment of wounds based on increased knowledge and the elimination of an overzealousness or overactivity which had been due to a lack of knowledge of fundamental principles. This overactivity had found its expression in the too free use of germicides, too much scrubbing and handling of wounds, which led in many instances to the spread of the infection which they were endeavoring to check. Many powerful germicides coagulated albumin, even when in solutions too weak to be effective as germ destroyers. A better procedure was to gently separate the edges of the wound, apply a weak solution of iodine, which was powerfully germicidal even in 1 per cent. solution and not injurious to the tissues, then paint the surrounding edges of the wound with a stronger solution of iodine, which would have a very positive germicidal effect upon the epidermis near the wound, and then apply a sterile dressing, and, what was always important but often forgotten, put the part at rest. Moist hyperemia should be used in infected wounds, and by that was meant cases where infection had taken place in the surrounding tissues. The purpose of the wet dressing was primarily to increase the resistance of the tissues and secondarily to facilitate drainage. The tendency to use wet dressings on all surface wounds came from the same meddlesome activity before referred to. Nature quickly threw out a coagulum over a wound, which was her way of preventing infection. This coagulum was easily soluble in plain water; thus nature's barriers were broken down and an easy portal of entry for infection established. For these reasons the dry treatment was preferable for all wounds not infected. In an infected wound the question was not one of germicides, but one of the resistance of the tissues. The object was to increase the nutrient elements in the blood plasma which tissues. Moist, warm hyperemia accomplished this end by combat infection and help toward the revitalization of increasing the number of polymorphonuclear neutrophiles and leucocytes. The moist dressing had additional advantages in that it required the minimum of handling and manipulation of the parts, and drainage was facilitated along the moist fibers of the gauze. To accomplish the physiological action the moist dressing should be a copious one, the whole forearm being covered in the event of an injury to a finger or thumb. The dressing should be moistened from time to time with some bland sterile solution. In granulating wounds with sluggish granulation such astringent and stimulating agents as red wash and balsam of Peru occasionally were useful. If these fundamental principles were followed there would be fewer permanently impaired hands, amputations, cases of pyemia, septicemia, and death following surface wounds of the body.

Dr. Parker Syms of New York outlined the way they treated wounds in the Lebanon Hospital. The preparations adopted for deliberate operations were practically the same as for emergency preparation of wounds. They began to use iodine preparation on the operation field and they still followed this plan. The skin surrounding the wound was gently swabbed with a solution of iodine in benzine; this was for the purpose of removing the dirty grease. Then the area involved was painted with tincture of iodine, or tincture of iodine in alcohol. The use of water should be avoided, as well as fluid soap or anything else within twenty-four hours of the time the iodine preparation was used. Water would swell the epidermal cells and prevent the infiltration of the superficial layers of the skin by the iodine and so prevent their attempts to disinfect the superficial skin by the use of the iodine. If iodine was used on a skin which had been macerated by water, or water and soap, there would be produced an annoying dermatitis. The solution used was tincture of iodine diluted one-half with alcohol. When Dr. Syms was house surgeon in Bellevue Hospital in 1881 he was fortunate enough to see a great evolution in surgery. In Dr. James Wood's ward the typical surgery of those old days was done. In amputations, for instance, the wounds were left absolutely open, no sutures being used, but a sufficient cuff of skin and tissues was left to cover; the resulting hole was filled with gauze saturated in balsam of Peru. That was the style in those early days. Those patients recovered with the loss of a limb and they lived in a fair proportion of cases. At the same time in Dr. Robert F. Weir's wards was introduced listerism. The dressing of a wound required no end of trouble and disaster to the patients. The method was carried out in a faulty manner. The wounds were dressed only when the discharge appeared outside the dressings, and the dressings were applied so that the discharge could not get out. During the six months Dr. Syms was junior they had to treat sixteen compound fractures, mostly of the leg; they were able to save one, possibly two. That was a frightful condition. It represented the most meddlesome kind of antiseptic surgery. Soon a surgeon from Esmarch's clinic introduced there the most successful method of antiseptic surgery. They then began to really disinfect the tissues. To-day the nearest they came to disinfecting the tissues was with the use of iodine; this not only disinfected the skin but also prevented reinfection of the wound. The healing of a wound depended upon physiological processes, and not on chemicals.

Some Popular Misconceptions Regarding Ophthalmia Neonatorum.—Dr. Ellice M. Alger of New York read this paper. After calling attention to the very prevalent neglect to make use of the simple remedies recommended for the prevention of ophthalmia neonatorum, he said that he did not believe this neglect was due to ignorance or carelessness, but proceeded from causes much less discreditable to head and heart. Every case of conjunctival discharge beginning during the puerperal period was at once regarded by the physician, the mother, and the friends as a certain proof of an antecedent infection of the mother, received, of course, through a delinquent husband. Now this was distinctly only about half true, and, like many other half truths, it had done a tremendous amount of harm. The gonococcus was only one of a number of germs that might cause ophthalmia. Everyone who had had smears made regularly from discharges in the eyes of new-born babies had probably been surprised by the failure to find the gonococcus in apparently typical

cases. On an average at least one case in every three was not of gonococcal origin at all. The venereal theory was one of the greatest obstacles to universal prophylaxis. The physician could not be handled like the midwife and told to obey orders simply because they were orders. He insisted upon using his powers of discrimination in individual cases. Sceptic though he often was of human virtue, he could not suspect all prospective mothers of harboring a latent gonorrhea, and that being the case he saw no logical need of a prophylactic instillation. Physicians often felt that in most cases of their patients and friends prophylaxis against a venereal disease was almost insulting and would certainly be so regarded if they were consulted. If they taught the absolute truth that ophthalmia was not necessarily a disgraceful occurrence and might be the result of any of the various pus germs, then physicians would at once see the advisability of prophylaxis in every case, while parents would no longer feel insulted at the suggestion of such a precaution. The gonococcus theory was also responsible for unfortunate misconceptions as to the severity and danger of the disease when it did occur, and led to serious errors in treatment. In the treatment of ophthalmia every precaution should be taken to preserve the integrity of the corneal epithelium; as a matter of fact the usual program of meddlesome interference would soon abrade the cornea of a perfectly healthy eye. Strong solutions of all sorts should be avoided, and likewise compresses and poultices which increased the pressure of the lids on the cornea. A clumsy or heavy-handed nurse might abrade the cornea in the frequent efforts to open the eyes and irrigate them. Even the advisability of hospital treatment was open to serious question. It should not be advised unless the child was certain to be neglected at home. The prognosis of any case depended upon the vitality and nutrition of the child more than upon any other factor. Physicians were taught to lay altogether too much stress upon the hospital, the oculist, and the bacteriologist. When a case occurred the main thing was to get the treatment started at once. Dr. Alger was accustomed to have the child brought to him every day, at which time, if it could be done without too much struggling, he tried to get a glimpse of the cornea and drop a drop of silver nitrate into the eye. The mother or nurse was instructed to cleanse the eye by sponging the closed eye with pledgets of cotton and boric acid as fast as notable secretions accumulated and the lids were prevented from sticking by applications of oil and vaseline. Every three hours a drop of 20 per cent. argyrol solution was instilled. Under treatment of this kind most cases improved from the beginning. One could not possibly disinfect an ulcer which was bathed in pus by carbolic acid, or iodine, or a caustic, but the destruction of an eye could easily be hastened by such means. The conservative treatment was best. The presence of corneal complications, while they made the prognosis worse, made no change in the treatment except that they called for the additional use of atropine.

A Talk on the Care and Training of the Feeble-Minded.—Dr. C. S. Little, Superintendent Letchworth Village, Thiells, said that the State of New York had purchased two thousand acres of land for the care and training of the feeble-minded. This was made necessary because soon they expected to have 3,000 inmates to care for. The plan of development was nearly completed. The patients were divided into six groups, three male and three female; there was one group for the improvable cases, one for the adult cases, and another for the infirm cases. Each group was in separate dormitories situated far apart, so that each dormitory might be considered an institution by itself. Each dormitory was arranged for the accommodation of fifteen to seventeen inmates. A careful classification of the cases was made. As to the care and training of the feeble-minded in the institution, he looked upon the institution as having four periods, as follows: (1) The home. They tried to supply, so far as was possible, the privileges the normal child was assumed to have in a normal home. Games were indulged in such as baseball, tennis, and other outdoor sports, and checkers, etc., indoors. (2) The school. This was the most important function of the institution and the schools were arranged according to the intellect of the individual. They had the kindergarten; they trained the use of the eyes, etc. Again, they had a group for school work, such as the study of geography, arithmetic, writing, and reading. One of the most important things was that these individuals should be doing something they were interested in. It did not matter so much if a feeble-minded child played baseball or did carpenter work so long as he was interested in it. (3) The workshop. They had an abundance of land where the boys could work outdoors and raise crops, dig ditches, and clear off the ground. They had industrial work in the laundry, in the sewing rooms, basket work, etc. (4) The laboratory. This feature was very important. An institution of that kind should be a place of science, where careful study could be made of the cases; just along what exact lines the speaker could not at present say. Many interesting studies had already been worked out with astonishing results. The education of the public was a very important matter. The families of the feeble-minded for five and six generations were found to have hundreds who had been supported by the State, who had committed crimes, and what not. This was especially an interesting study. This class of cases should be segregated permanently. If they really were going to do anything worth while it settled itself down to the movement similar to what was instituted in tuberculosis. This class of cases must be segregated and kept away from the community.

Election of Officers.—*President,* Dr. Daniel Bailey Harderberge of Middletown; *Vice-President,* Dr. John Calhoun Otis of Poughkeepsie; *Secretary,* Dr. Charles Ellery Denison of New York; *Treasurer,* Dr. George Swan Mooney of Yonkers.

AMERICAN NEUROLOGICAL ASSOCIATION.

Thirty-seventh Annual Meeting, Held at Baltimore, Md.

The President, Dr. H. M. Thomas of Baltimore, in the Chair.

(*Concluded from page 650.*)

Acute Chorea Characterized by Motor, Physical, and Mental Symptoms.—Dr. Allen Ross Diefendorf of New Haven, Conn., read this paper, saying that in chorea the mental symptoms might be classified as mild forms and as choreic psychoses of chorea insaniens. The mild forms predominated and affected principally the emotional sphere. Their intensity was usually proportional to the severity of the motor signs, and their prognosis was good. The choreic psychoses were rare and the predominating form was a state of delirium occasionally terminating in fatal stupor, and less often in a paranoid condition. A stuporous state was another less frequent and more grave form. These groups were not to be confounded with chorea complicating dementia paralytica, senile dementia, dementia præcox, or manic-depressive psychoses.

A Case of Pseudo- or Diffuse Sclerosis.—Drs. Theodore Diller and George J. Wright of Pittsburg, Pa., read this paper. Westphal described in 1883 an affection which he called "pseudosclerosis," which bore a close resemblance clinically to disseminated sclerosis, but differed from it chiefly in that it was characterized by progressive dementia. Rebizzi had studied clinically and anatomically

a classical case of pseudosclerosis. He concluded that pseudosclerosis and diffuse sclerosis were manifestations of the same disease process and should be considered as one disease, due to a diffuse primary affection of the nervous elements, with secondary increase of the glia cells. Their own case was that of a boy, aged 13, who had developed normally up to the age of 9, when his present illness began, and had steadily and slowly progressed up to the present time. It was characterized by gradually progressive mental deterioration, and during the last three years by change in his speech. For the past two years there had been progressive muscular weakness so that now the boy frequently fell in attempting to walk. At present he was dull and apathetic and unable to count up to twenty or to write his name. He exhibited marked speech defect and tremor of peculiar character, suggesting intention tremor of disseminated sclerosis. The knee-jerks were exaggerated; Babinski toe reflex present on both sides; eyegrounds normal; no ocular palsies; no nystagmus; spinal fluid normal. From a diagnostic point of view the case was to be differentiated from juvenile paresis and disseminated sclerosis.

Dr. William G. Spiller of Philadelphia had once examined the brain in this disease. The condition was so striking that he did not think anyone could make a mistake in recognizing the disease when he had the brain before him. The brain felt as hard as if placed in some hardening fluid like formalin. One could not exclude in Dr. Diller's case a possibility of nodular gliosis. It was possible that there was some form of encephalitis of a chronic type or degeneration going on which would also give the symptoms reported. It was even possible that it was a multiple sclerosis.

Saturday, May 15—Third Day.

The Temporal Lobe Detour of the Optic Radiations and Its Importance for the Diagnosis of Temporal Lobe Lesions.—Dr. Adolf Meyer of Baltimore, Md., demonstrated a further case of division of the optic radiations into isolated bundles furnishing proof that the external sagittal marrow of the occipitotemporal lobe consisted essentially of geniculocalcarine fibers and that its ventral part alone formed a detour toward the uncinate region within the temporal lobe. Lesions of the anterior part of the temporal lobe if sufficiently deep, therefore involved the most ventral bundle of the optic radiation, and implied a defect in the upper quadrant of the visual field. As clinical evidence he would refer to a case of Dr. Cushing's of an old bullet wound through the orbit in which the bullet was lodged upon the petrous bone and in which this defect of the upper quadrant was clearly established, but so close to the median line that it could easily have been overlooked in a hasty perimeter examination. It was expected that the facts reported should, once for all, refute the opposition of the von Monakow school concerning the existence of the detour, and added a valuable help to the diagnosis of the temporal lobe lesions.

Remarks on States of Experimental and Clinical Dyspituitarism.—Dr. Harvey Cushing of Baltimore, Md., read this paper, stating that he would illustrate his remarks with a series of lantern slides and trace the steps of recent advances in the knowledge of the function of the pituitary gland. The structure as a whole was essential to the maintenance of life. The relationship of the pars anterior to body growth was indicated by the infantilism persisting in animals after partial removal of the gland early in life. Experimentally produced glandular deficiency (hypopituitarism), furthermore, led to an abeyance of the sexual function, to hypotrichosis, a tendency to a subnormal temperature, adiposity, and an increased tolerance for carbohydrates. The condition, in other words, indicated a lowered oxidizing or metabolizing capacity on the part of the organism. Practically normal metabolic conditions could be restored by administering glandular extracts. Studies, in conjunction with Emil Goetsch, had shown that the posterior lobe secreted into the cerebrospinal fluid concentrated solutions of the normal fluids, exhibiting all the properties of extracts of the posterior lobe itself. Hence studies of the cerebrospinal fluid from this standpoint would indicate, he hoped, the degree of posterior lobe over and under-activity in the individual case. The fluids obtained from the abattoir might indeed prove to be of therapeutic value. These experimental findings had shed light on many hitherto obscure clinical conditions, particularly in so far as they related to states of hypophyseal underactivity. He showed lantern slides of 40 cases of pituitary disease under observation during the past two years, and in all probability recognizable clinical states of altered hypophyseal activity were just as common, if not more common, than those of altered thyroid activity. In the past only a small group of outspoken cases received clinical recognition. He classified the cases into groups, according to the presence or absence of (1) neighborhood symptoms, (2) general pressure symptoms, and, (3) marked glandular symptoms 1. *Neighborhood Symptoms*—Except in the presence of outspoken acromegaly or gigantism few ventured to make a diagnosis of hypophyseal disease unless an interpeduncular or hypophyseal tumor was obviously present. The tumor, however, were it a primary adenoma (hyperplasia) of the gland associated with a state of hypersecretion or, on the other hand, an interpeduncular growth which compressed the gland and obstructed its secretory activity, or a primary hypophyseal growth which had finally destroyed the gland's secretory powers—the tumor, to repeat, was merely a fortuitous association, without which in all probability the syndrome of Marie (acromegaly) and that of Frölich (dystrophia adiposogenitalis) would never have come to be attributed to a functional disturbance of the pituitary body. The neighborhood symptoms of chief moment were primary optic atrophy with a tendency to either a bitemporal or homonymous hemianopsia (more often the latter), oculomotor palsies, exophthalmos, possibly uncinate fits, epistaxis, and the like. The *x*-ray would often show an absorption or enlargement of the sella turcica, it being necessary to take stereoscopic plates if an accurate estimate of the sellar configuration was to be obtained. 2. *General Pressure Symptoms*—These might occur when the growth or glandular hyperplasia burst through the confines of the gland's dural envelope or when a primary interpeduncular growth, usually arising from a congenital anlage, enlarged sufficiently to obstruct the foramina of Monro. They were similar to the pressure phenomena of other intracranial tumors. A choked disc became superimposed on the primary atrophy. These matters relating to local and general intracranial pressure might be helpful in making a diagnosis; but far more important, inasmuch as they occurred in the absence of recognizable tumor or enlargement, were the next group. 3. *Glandular Symptoms*—The 40 cases were presented on the basis of clinical states brought about by over and under-activity of the anterior lobe and by over and under-activity of the posterior lobe. Furthermore, it must be realized that a different clinical picture resulted when the malady originated before or after adolescence. Hence there were eight fairly definite types which would probably be recognizable, though they would overlap to a greater or less extent. Thus the syndromes of acromegaly and gigantism were presumably occasioned by a condition of over-activity of the pars anterior. Coincident with this condition, however, there might be a state of over-activity or of under-activity of the posterior lobe. Hence mixed types were to be met

with. The investigation of the sugar tolerance of these individuals had shown that in time they acquired an extraordinarily high assimilation limit, indicating an ultimate posterior lobe insufficiency. It had long been known that spontaneous glycosuria was a frequent accompaniment of the acromegalic syndrome, but it appeared that this was only true of the early stages of the disease, the tendency in all cases being toward an ultimate over-tolerance for carbohydrates. Far more common apparently were the cases which showed, from the onset, evidences of glandular hypoplasia and gave symptoms comparable to the experimental states following partial extirpation. Some of the more striking of these symptoms were amenorrhea or impotence, a subnormal temperature, a low blood-pressure, polyuria, loss of hair, a dry skin, and a generalized adiposity which was presumably coupled with the acquirement of a high assimilation limit for sugars. When the process started early in life the secondary sexual characteristics were imperfectly acquired and there was a persistence of infantilism. In the adult there was a tendency to revert to the condition with atrophy of the gonads. A feminine type of body configuration occurred. It could not be too strongly emphasized that any functional alteration of the hypophysis led to changes in all of the other ductless glands. This was true of the experimental as well as the clinical states. It was true also for primary alterations in other glands—thyroid, adrenal, and so on. The syndrome therefore was a polyglandular one, in the sense of the French writers, in every case of ductless gland disease, no matter which of the glands was primarily affected. There was, however, a dominant clinical picture which accompanied a state of over- and of under-activity of each individual member of the series. These states of hypopituitarism were brought about by (1) a primary glandular hypoplasia from developmental failure or early disease; (2) a condition of hypoplasia due to destruction of the gland from an advancing primary tumor; (3) the direct pressure upon the gland from a superimposed interpeduncular tumor; and (4) distant lesions which produced an internal hydrocephalus and thus dammed back the cerebrospinal fluid, which had been shown to be the medium holding posterior lobe secretion. The therapeutic indications were simple: A large tumor producing neighborhood symptoms called for surgical decompression or partial removal for preservation of vision and relief of discomfort. (Complete enucleation of a tumor which had burst the bounds of the sella was, of course, impossible, and complete emptying of the sella was unsafe, for there might be some viable and normally functionating anterior lobe remaining.) All cases of glandular insufficiency, recognizable on the basis of adiposity and increased sugar tolerance, called for glandular administration. The dosage should be regulated on amounts of the extract sufficient to produce hyperglycemia with a dosage of sugar which should represent the assimilation limit of a normal individual of the same ago and body weight. Three recent operative cases still resident in the hospital were shown, two of them cases in which merely a sellar decompression had been performed by a sublabial route; in the third the large portion of a tumor had been removed. In all of them supplementary glandular feeding was indicated, as they were all in states of hypopituitarism.

Leontiasis Ossea, Acromegaly, and Sexual Infantilism.—Dr. Herman H. Hoppe of Cincinnati, Ohio, read this paper, stating that acromegaly had an undoubted relation to disturbances of the hypophysis that the many cases on record of tumor and disease of the hypophysis clearly showed, and was so universally accepted that they always expected a tumor of the hypophysis when they diagnosed the condition clinically. But the fact that hypophysis tumor often occurred without causing acromegaly seemed to indicate that whatever disturbance was caused in the functions of the hypophysis might be vicariously neutralized by some of the other ductless glands. Moreover, cases like theirs seemed to indicate that either excessive actions of the hypophysis could exist without marked increase in structure, or that the normal action of the gland could be inhibited by the action of some other ductless glands and that the clinical picture, as they had it in their case, was one of hyposecretion. One fact, however, stood out prominently in this discussion: There were few cases of acromegaly on record in which some changes were not found in the hypophysis. On the other hand, changes in the other ductless glands were not at all constant, and hence the line of investigation would continue in the direction of pathological changes in the hypophysis. From a standpoint of therapeutics their case offered very little instruction. The only remedy for hyperactivity was to remove the gland. If they held the theory of defective activity, they might feel that some results could be obtained in beginning cases by administering the extract of the anterior lobe. There was at least one series of experiments of this kind in which good results were obtained. He referred to the article of Kuh. On the other hand, the experiences of Salmon, Magnus-Levy, Schiff, and Franchini, in feeding large quantities of pituitary tablets, either in health or disease, were negative.

Dr. C. K. Mills of Philadelphia said that he had under observation for one to two or more years three cases in which he had made the diagnosis of tumor of the uncinate region, which he thought had a distinct bearing on two or three points brought out by Dr. Cushing in his admirable presentation. Each of his three cases had the classical syndrome of Hughlings Jackson, namely, the presence of taste aura with the occasional occurrence of conditions of automatism and a more or less dream state. In only one instance had the patient any visual symptoms. In one of those cases there had been a temporary partial homonymous hemianopsia. In none of the cases had there been any papilledema, and in two of the cases headache had been well marked.

Remarks on Methods of Curing Idiopathic Epilepsy.—Dr. L. Pierce Clark of New York read this paper, saying that he could find but a few scanty notes of actual reported cases of cured idiopathic epilepsy. Statistics and percentages of cures were of no value unless backed by actual data. The time limit which constituted a cure must be invariably supported by physical and mental changes to constitute a criterion of arrest or cure. The patient should be self-regulative, there should be a disappearance of the physical anomaly of metabolic defect and an absence of the psychical stigma of the disease. The word *cure* should be dropped and *arrest* substituted instead. So-called spontaneous cures were almost invariably brought about by the self-reliance of the patient upon a hygienic system more or less adequately adhered to. Special drug therapy, especially the sedative, was thoroughly discouraged in treating idiopathic epilepsy. Neither had the bromides improved the prognosis. These should be limited to a therapeutic determination of the severity of the disease and in intractable hopeless cases. He had presented in detail his method of hygienic treatment in an illustrative case which covered a form of intensive study and training-treatment along the lines of diet, rest, occupation, and exercises. He believed that 75 per cent. of all idiopathic epilepsies showed some metabolic defect. No case had recovered showing real mental deterioration. The rather frequently reported cures at four or five years of age were probably but reflex convulsions, but many such might in time develop into genuine epilepsy if they were not checked. Spontaneous cures rarely occurred between five or six and twenty years of age. The chances

of spontaneous cures improved greatly with advancing years, between 20 and 40 especially. Relapses in cured cases were not common even after 15 or 20 years of arrest. The cause for relapses was a breaking away from the hygienic regimen, emotional and mental stress. Restoration to a second arrest was very difficult of accomplishment.

Dr. James J. Putnam of Boston, Mass., said he had tried the hygienic treatment without bromides in several instances and had been very well satisfied with the results and meant to continue it. He had begun already to include in lectures to students that if they were going to rely on hygiene they must carry it to the point of adoption, something equivalent to the careful training of a person to enter on some sort of athletic contest.

Psychanalysis and Correction of Character.—Dr. E. W. Scripture of New York read this paper. (See page 859.)

Dr. Philip Coombs Knapp of Boston, Mass., said that the entire question of psychanalysis had, in spite of all one had heard about it, hardly reached the stage from which one could draw definite scientific deductions. Their technique was by no means perfected in regard to all these points. They had not yet very definite data on which to analyze the mind. In the second place, they had not yet enough data in regard to the occurrence of various symptoms. He was perfectly willing to confess that much of this psychanalysis seemed to him exceedingly vague and speculative, exceedingly untrustworthy, and anything but scientific.

Dr. Ernest Jones of Toronto, Canada, said the subject was so very large that it was difficult to discuss it without formulating some particular concrete point upon which inquiry was to be raised.

Sudden Loss of Weight and Pneumonia.—N. Berend has observed that infants who, as the result of diet, are subject to a sudden loss of weight are particularly liable to develop pneumonia, even in the absence of any exposure to infection.—*Monatsschrift für Kinderheilkunde.*

Surgical Treatment of Adenoid Vegetations and Hypertrophy of the Tonsils.—Aristide Malherbe and Robert Jouet think that medical treatment of adenoids and hypertrophied tonsils is illusory; as soon as the diagnosis of adenoids is made they should be removed, unles there is present an attack of adenoiditis or of an infectious disease. Anesthesia should be employed always if we desire to make a complete operation. The best is chloride of ethyl; this produces rapid narcosis and a sound and quiet sleep. There are no disagreeable after effects, no nausea or vomiting and kidney troubles. The anesthetic is better controlled when used with a simple compress than with a cone. The child should be placed in the Rose position, on his back, with his head extended below the level of the table. This position avoids the passage of blood and of debris from the vegetations into the windpipe. A special apparatus constructed for the author consists of a ring of steel screwed to the table, with two loops so placed that the head may be controlled by a napkin folded and passed through them, there being a concave crosspiece behind the head. A sharply curved curette is used for the removal of the adenoids. After the first inspiration of the anesthetic there is no further resistance; anesthesia is complete after four or five inspirations and resolution is rapid. The removal of the tonsils may be done with a tonsilotome, in cases of projecting tonsils, and after loosening them from the pillars of the fauces when they are flat and adherent. The two operations should not occupy more than three minutes; the child remains in bed for twenty-four hours and in the house for a week.—*Le Bulletin Médical.*

Medicolegal Notes.

General Alopecia Caused by Fright or Nervousness.—In an action for personal injuries to a girl of fourteen years of age whose dress was caught in a machine near which she was standing, the lever attachment of which struck her in the face with sufficient force to cause a slight abrasion, it appeared that she was nervous and hysterical for several days and at intervals thereafter for several weeks. About ten days after the accident her hair began to fall out very rapidly and within three weeks after the accident her body was devoid of hair and substantially remained so for four years, up to the time of trial. The medical testimony on the trial was to the effect that alopecia universalis, or general baldness, is a mysterious trouble, and the theory of its origin is obscure and conjectural; that medical authorites generally agree, however, that sometimes the trouble has a neuropathic origin, such as nervous shock, fright, or grief; sometimes, and in the larger percentage of cases, it is due to parasitic or germ disease, and sometimes it is attributable to heredity. From this evidence, together with the evidence concerning this particular case, it was held that the jury were warranted in finding as a fact that fright and nervous shock are an adequate cause for a condition of general baldness. The relation of cause and effect may be established, though the theory of such relationship is not understood. It is a matter of general information that the causes of morbid processes are still unknown in many diseases. Yet it does not follow that medical science is always unable to ascribe the development of such diseases to the existence of certain conditions. The testimony in this case was that by a general consensus of opinion of medical authorities it was recognized and established that this trouble did have its origin in fright and nervous shock. A court cannot assume, either, that this conclusion is not well founded, because the morbid processes involved are not understood, or that this conclusion of medical experts is based on insufficient data, because the experience and observation of laymen do not furnish sufficient data to establish such conclusion.—Oninsky v. Chas. Weinhagan & Co., Minnesota Supreme Court, 129 N. W. 845.

Opinion as to Continuance of Pain from Injury.—In an action for damages for personal injuries the plaintiff had testified that she had suffered a constant pain in her left side as a result of the fall. The accident occurred on March 2, 1907. A physician called as a witness on her behalf testified that he performed an operation upon her for fixation of the kidney and removal of the right ovary in August, 1906, but that she had recovered from the operation. It was held that he might give his opinion in reply to a hypothetical question, assuming that she had not any pain in her left side prior to the accident, as to how long the pain she suffered from the injury would continue, as against the objection that his opinion was speculative; but he might not give his opinion as to future apprehended conditions.—Cross v. City of Syracuse, New York Court of Appeals, 200 N. Y., 393, 94 N. E. 184.

Nebraska Rule as to Privileged Communications.—The Nebraska court holds that in a contest over the probate of a will between the person therein named as an executor or a legatee and the heirs at law of the decedent Section 333 of the Nebraska Code of Civil Procedure, forbidding the disclosure of privileged communications, does not prevent a physician from testifying on behalf of either side of the controversy to the mental condition of the testatrix, though the information which enables him to do so was acquired solely in his professional capacity while attending her during her last illness.—In re Gray's Estate, Nebraska Supreme Court, 130 N. W. 746.

Presumption of Continuance of Insanity.—In a will contest an instruction that all persons are of sound mind who are neither idiots, nor lunatics, nor affected with insanity, was held not erroneous as measuring the mental capacity to make a will. But an instruction that, where the testator is shown to have been insane before and after executing a will, the proponent is bound to show that it was executed when the testator was of sound mind, was held to be erroneous as fixing the burden of proof on the proponent.

Under Montana Rev. Codes, Sec. 7062, subd. 32, providing that a thing once proved to exist is presumed to continue as long as is usual with things of that nature, lunacy, or insanity, if of a general, habitual, or permanent nature, once shown to exist, is presumed to continue until the presumption is overturned by countervailing evidence. That rule is recognized by the courts gen-

erally. But to cases of intermittent or occasional insanity the rule can have no application because in the very nature of things the idea of continuity is excluded. So that when this is the condition proof of its existence at one time raises no presumption that it existed either at an antecedent or subsequent time.

If a testator was of sound mind at the time his will was executed his precedent and subsequent condition is immaterial.—*In re* Murphy's Estate, Montana Supreme Court, 116 Pac. 1004.

Evidence of Insanity—Prior Acts—Family Taint.—Where the issue to be determined by the jury is the mental condition of a person at a certain time, it is always competent to show previous acts of insanity, delusion, or mental derangement, unless the previous conditions are excluded because they appear to be disconnected and remote. Where insanity is continuing or permanent in character, or where the cause of the disorder is continuing or permanent, the objection of remoteness will not apply. In Kansas it is well settled that a non-expert witness may be permitted to give his judgment as to the sane or insane state of another's mind after having detailed to the jury the extent of his opportunities to deduce a correct opinion and judgment thereon.

Proof of a taint of insanity in the family of a person is generally held admissible on the recognized principle of the hereditary character of insanity, but only in corroboration of proof that a particular person is, or was, insane. But such proof without actual evidence of insanity in the person himself will never be allowed to overcome the presumption of his sanity. It is competent only when there is other proof tending to establish the insanity of the person in question.—Fish v. Poorman, Kansas Supreme Court, 116 Pac. 898.

Competency as Medical Expert.—In an action for damages for the death of a daughter, alleged to have been caused by breathing the poisoned atmosphere from the defendant's hide-curing establishment in the same block, it was charged in the petition that hides were hung up by the defendant in the open air in a decaying condition; that the air was impregnated with it; that it produced disease, was ruinous to health, and poisonous to the human system. It was held proper to allow a physician to state the effect of decaying meat upon the surrounding air and upon any one breathing it.—A. Cohen & Co. v. Rittimann, Texas Civil Appeals, 139 S. W. 59.

Expert Opinion as to Mental Condition.—An exception to the general rule as to the opinion evidence of experts is admitted in the case of medical experts testifying to the mental condition of a party where the particular facts upon which the opinion is based need not be disclosed in the first instance.—Weibert v. Hanan, New York Court of Appeals, 95 N. E. 688.

Father's Right of Action for Injuries to Minor Son in Setting Arm.—An action was brought by the father of a boy five years of age against a physician and surgeon alleging unskillful treatment in attempting to set the boy's arm resulting in permanent crippling and uselessness of the forearm and hand. The plaintiff sued for expense incurred and which must be incurred to partially save the forearm and hand and also for the loss of his son's services until he should come of age. It was held, against demurrer, that the father had a right of action.—Otey v. Bradley, Washington Supreme Court, 115 Pac. 1045.

Father's Duty to Furnish Medical Attendance to Children.—In a prosecution against a parent for wilfully omitting, without lawful excuse, to furnish medical attendance to his minor child, it appeared that the child was afflicted with typhoid fever, and the county health officers had endeavored to induce the defendant to permit the child to be attended to by physicians and nurses, but he had refused, although the medical attendance was offered without expense. Under the Oklahoma statutes it is the duty of a parent having the custody of a minor child to support and educate the child; and such "support" includes necessary medical attendance to preserve the health and life of such child. A reasonable construction of the statutes would require the furnishing of medical treatment in such a manner and on such occasions as an ordinarily prudent person solicitous for the welfare of his child and anxious to promote his recovery, would provide. In a case for a violation of a statute which provides that "every parent of any child who willfully omits, without lawful excuse, to perform any duty imposed upon him by law to furnish necessary food, clothing, shelter, or medical attendance, for such child, is guilty of a misdemeanor" the question of the necessity for medical treatment is one of fact for the jury under proper instruction of the court.—Owens v. State, Oklahoma Criminal Court of Appeals, 116 Pac. 345.

SURGERY OF THE COMMON BILE DUCT.*

By JOHN B. DEAVER, M.D., LL.D.,

PHILADELPHIA, PA.

THE common bile duct may well be called the crucial point of the whole biliary system. It furnishes the one outlet for the biliary secretion and by the anatomical relations of its terminus wields an important influence over the pancreatic function.

The surgery of the duct not only presents difficulties entirely foreign to procedures upon other portions of the biliary apparatus, but is a subdivision of upper abdominal surgery which may tax the surgeon's patience, skill, and knowledge to the fullest extent.

First a word regarding the relational anatomy of the common bile duct. The common duct is formed by the junction of the cystic and hepatic ducts. The first portion of the common duct runs between the two layers of the right free border of the gastrohepatic omentum with the hepatic artery to the left and the portal vein behind and between the duct and the artery.

The duct may be divided into three portions: (1) the supraduodenal, the largest portion lying as described above; (2) the retroduodenal or pancreatic portion, which courses behind the duodenum and in one-third of the cases lies in a groove upon the surface of the head of the pancreas, between the head and the descending duodenum, and in two-thirds of all cases is, for at least a portion of its extent, entirely surrounded by pancreatic tissue; and (3) the intraparietal or interstitial portion, which is that portion of the duct contained in the thickness of the wall of the duodenum.

The terminal portion of the duct dilates within the duodenal wall into a little pouch called the ampulla of Vater and into this the duct of Wirsung also empties. The normal average of the ampulla is one-sixth of an inch, although it may be as large as two-fifths of an inch in diameter, or again, may be absent altogether. Besides the usual arrangement of both the common bile duct and the main pancreatic duct entering the ampulla in the manner described, the ducts may join some distance from the duodenal wall, or they may separately pass through the duodenal wall; in either instance the ampulla of Vater being absent. The average diameter of the common bile duct is given as that of a goose quill and its average length 2 2/5 to 3½ inches. The narrowest portion of the duct is at the orifice of the papilla in the duodenal wall which furnishes the outlet to the ampulla of Vater.

There are three anatomical features not often mentioned in the text-books with regard to the common duct which I have found to be of considerable importance. The portal vein occasionally lies immediately behind and slightly to the right of the duct and sometimes projects upward far enough to partly cover it. It is my practise, when in doubt, to use a hypodermic syringe to determine by aspiration whether the presenting structure is the bile duct or the portal vein. Puncture of the vein by a hypodermic needle is of no moment, but without this careful precautionary measure incision may bring disaster.

The point of junction of the common and hepatic ducts varies considerably. In the classical arrangement a Y junction is formed and we have the supraduodenal portion of the duct running alone as the final biliary passage. In a considerable number of instances, however, I have found the junction of the cysticus and hepaticus much nearer the duodenum, with the hepatic opening situated posteriorly in such a manner that it appeared more like a tributary of the common duct rather than as one of the main constituent branches. This arrangement of the ducts must be kept in mind. Ordinarily it is easy after opening the common duct to explore by probe the hepatic duct, but with the arrangement just mentioned it may become a matter of difficulty to locate the hepatic duct if this arrangement is not borne in mind.

In intimate relation with the common duct are lymphatic vessels and glands, the latter varying in number from three to a half-dozen or more. This arrangement provides a lymphatic connection between the gall-bladder and under surface of the liver and the head of the pancreas. The clinical importance of these relations I shall later point out.

This brief discussion of the relations of the common duct to the other upper abdominal structures will, I trust, make it clear that he who would attempt to deal with this structure should be entirely familiar with its anatomy. Even under normal conditions the dissection of the common duct may be difficult—how much more difficult will it be in a patient in whom pathological conditions have supplanted the normal!

The pathological abnormalities of the duct which require operative interference, excluding traumatic lesions, may be grouped generally as those in which there is either a complete or a partial obstruction to the flow of bile through the duct with the consequent train of symptoms due to this condition acting alone or in conjunction with the underlying lesion. And since obstruction of the biliary discharge causes jaundice and its accompanying phenomena we may briefly describe the conditions demanding operative interference upon the common duct as those in which there is jaundice, constant or intermittent, due to common bile duct obstruction.

Practically all of the cases of common duct ob-

*Read before the Hudson County Medical Society, Jersey City, N. J., October 3, 1911.

struction are due to one or more of the following causes: (1) Gallstones; (2) pancreatitis, whether by the tumefaction of acute inflammation or by the stenosing cicatrization of a chronic process; (3) cancer of the duct, its papilla, or the adjacent duodenum; (4) cancer of the head of the pancreas; (5) cicatricial stenosis of the papilla due to duodenal ulcer; (6) stricture of the duct due to ulceration associated with the presence of a stone, or occasionally following operation necessitating incision or drainage of the duct; (7) pressure from adjacent structures; (8) hydatid cyst or membrane.

It is manifest that groups 1, 2, and 4, *i.e.* gallstones, pancreatitis, and cancer of the pancreas furnish us with most of the cases requiring surgery of the common duct. And in cholelithiasis, with or without the association of a pancreatitis, we have so far found the commonest cause for surgery of the common duct.

In a consideration of cholelithiasis of the common duct there are several factors which we must take into consideration.

The first is the comparative frequency of stone in the common duct to gallstone cases of all kinds. In 626 cases of gallstones operated upon at the German Hospital, stones were found in the common duct in 139 cases, or 22 per cent. plus, of all the cases. Of these the distribution of the stones was as follows: Gall-bladder and common duct, 68 (48 per cent.); gall-bladder, cystic, and common duct, 5 (3.5 per cent.); gall-bladder, common, and hepatic ducts, 5 (3.5 per cent.); cystic and common duct, 1 (0.7 per cent.); common duct alone, 44 (31 per cent.); gall-bladder, cystic, common, and hepatic ducts, 5 (3.5 per cent.); common and hepatic ducts, 11 (7.8 per cent.). These figures make it evident that anyone attempting to do gall-bladder surgery must be fully prepared to do any necessary procedure upon the common bile duct as well.

At the present time it is a rarity for an experienced surgeon to overlook the presence of gallstones in any portion of the biliary tract at the time of operation, yet a number of instances have been recorded in which this has occurred, and I have encountered them personally. Particularly is a stone likely to be overlooked in the second portion of the common duct if it be enveloped by pancreatic tissue or in the terminal part of the duct near the papilla unless to our sense of touch we add also thorough probing of the duct.

Common-duct cholelithiasis is always a sequel of gall-bladder lithiasis. That is to say, we have no evidence which would tend to show that stones are formed within the common bile duct itself, or, for that matter, in any of the other ducts. Stones found in the normal common duct are formed within the gall-bladder and pass, while comparatively small, down into the cystic and thence into the common duct. There has been some question of the possibility of the formation of gallstones within the hepaticus or within the smaller intrahepatic passages, but it is probable that most intrahepatic stones are passed from the gall-bladder into the cystic and common ducts and then pushed back into the hepatic. There is, however, no doubt that a stone once lodged in the common duct may there increase very greatly in size. Cases of very large stones within the common duct and removed at operation have been reported of late by H. R. Wharton[1], and J. M. Deacon[2] who reports a stone 2¼ inches long by 4 inches in circumference found in the common duct, and Carwardine[3] who reports a stone 3½ inches long and 4 inches in circumference.

The distensibility of the common duct may well excite surprise; under the influence of a constant distending force the dilatation may be enormous, as in a case of cystic enlargement reported by Weiss[4] occurring in a boy six years old. Rupture does not occur unless the duct wall is weakened by ulceration, necrosis, or the force is suddenly and violently applied as in direct traumatism.

As a relatively common condition the symptomatology of stone in the common duct has often been depicted. Mr. Mayo Robson has well summarized the cardinal symptoms as follows: (1) Jaundice of varying intensity, deepening after each paroxysm, which may persist for months or years; (2) ague-like paroxysms, characterized by chill, sweating, and fever and followed by deepening of a persisting jaundice; (3) at the time of the paroxysms pain in the region of the liver with epigastric distress.

These are exactly the symptoms as furnished by Osler and in practically the same words. The febrile disturbance is also sometimes called the hepatic intermittent fever of Charcot. Naunyn, many years ago, also noted these symptoms, and adds the more valuable one of normal size or only slight distension of the liver and enlargement of the spleen.

These symptoms require some discussion and cannot be accepted as a set form of rules suitable for the diagnosis of every case.

The jaundice in stone in the common duct is in some cases a very slight symptom, in others a most noticeable one. But while there are a considerable number of gallstone cases which never show jaundice, it is rare for a case of common-duct stone to be entirely free of this condition. Even this may occur, however, as pointed out by Kehr. In most of the instances jaundice is an early and persistent symptom. There can, however, be no doubt of the variability of the jaundice in common-duct cases, and here we have an important diagnostic feature. In jaundice due to malignant disease of the head of the pancreas or even marked interstitial pancreatitis, the condition is constant and progressive. Malignant pancreatic conditions usually show a peculiar and characteristic greenish tinge. Associated with severe jaundice we, of course, have the presence of bile in the urine and its absence in the feces.

The pain in common-duct stone is said to be less severe than in other forms of gallstone disease, being more pronounced in the epigastric region; the pain is referred to the back and not to the right subscapular region. The tenderness felt, if there be a tender point, is in the epigastrium rather than in the right hypochondrium.

The intermittent attacks of fever and chills often occurring with great regularity are a valuable sign of stone in the common duct, yet by no means so constant or typical as they have been pictured. Of all the symptoms, I should class pain as by far the most constant and as a distinguishing feature of common-duct stone remittent and severe jaundice.

Mayo Robson and Cammidge state that the pancreatic or so-called Cammidge reaction was found by them in 60 per cent. of their common-duct cases. This reaction in my experience, embracing now about 400 cases in which the reaction was tried, has not yet shown itself to be sufficiently valuable to have much weight in the diagnosis of common-duct obstruction of gallstones.

The diagnosis of gallstones is by no means easy in all instances, since, as Moynihan has well remarked, there is no symptom or group of symptoms due to gallstones which may not be exactly simulated by some other condition. Granted, however, that gallstone disease may fairly be established, the differentiation of common-duct stone from other varieties can usually be made. That which gives the greatest trouble is to differentiate stone in the common duct from other non-calculous conditions which may more or less accurately reproduce its symptomatology. The chief conditions of this sort which require careful distinction are cancer of the pancreas and chronic pancreatitis.

The main differences presented by the latter conditions in their usual manifestations are: (1) The absence of pain, or if present its lack of prominence as a symptom; (2) the progressive and ultimately deep character of the jaundice; (3) the demonstrable enlargement of the gall-bladder as stated in the well-known law of Courvoisier.

It is well to know, however, that the most typical course of common duct stone may be simulated by chronic pancreatitis. I have reported elsewhere a case operated upon within the past year in which following a cholecystostomy for gallstones the patient had been subject for five years to intermittent attacks of epigastric pain accompanied by chill, fever, sweating, and sometimes vomiting, followed by a deepening of the slight icteric tinge which was almost constantly present. Our diagnosis was stone in the common duct, but at operation no stones were found but merely a pancreas, the head of which was enlarged almost to the size of a man's fist. Cholecystostomy with prolonged drainage relieved the condition and up to the present this patient has remained well.

The diagnosis of common duct cholelithiasis having been made, the question of treatment at once presents itself. There is no medical treatment for the condition unless we include under this heading such measures as may be taken to prepare the patient for operation. Paroxysms of pain must be controlled by morphine and hot fomentations, with a careful regulation of the diet and bowels. It must be remembered that a stone rarely causes complete occlusion of a biliary duct, except it be the cystic, unless we have in addition inflammatory congestion of the mucosa of the duct to complete the closure.

I have always contended that operative treatment includes a thorough study of the case and a proper preparation of the patient for operation. The surgeon should endeavor to discover whether there be any organic disease of the heart, kidneys, or lungs so grave as to preclude operation. I believe that with a carefully given anesthesia, or when this is impossible the use of stovain intraspinally, there are but few truly inoperable conditions of the biliary tract which are made so by the patient's general condition.

Should the pulse be weak the careful use of digitalis prior to operation will often save much anxiety afterward. If the kidney excretion be either deficient in quantity or altered in quality attention should be given to this phase of the patient's condition before operation so that he be not handicapped by kidney insufficiency in his recovery. I cannot lay too much stress upon the latter point. If the copious ingestion of water does not give rise to free diuresis and the passage of approximately normal urine I often supplement this by hypodermoclysis or saline enemas or at times by continuous proctoclysis. The quality of the urine is not of as much importance by any means as is the quantity. Practically all cases of common duct obstruction, if at all sick, have more or less toxic nephritis, the urine showing hyaline and granular casts; this matters but little from the standpoint of operation if the kidneys are functioning freely, therefore why the great importance of determining this before operation?

But the gravest obstacle to the success of the surgeon is deep jaundice with its accompanying cholemic state. This is detrimental to the patient at and after operation in several ways. In the first place jaundiced patients are prone to hemorrhage. The cause of the hemorrhage tendency is obscure. It may be shown that chronic jaundice often delays the coagulation time of the blood. This undoubtedly favors hemorrhage. On the other hand the danger of bleeding bears no constant relation to the coagulation time. I have repeatedly observed intractable oozing in cases where the coagulation time as measured previous to operation was practically normal, and per contra I have much more often seen the most satisfactory freedom from hemorrhage in cases whose coagulation time was much delayed and our apprehension greatly increased thereby. It seems likely that some condition of the vessels themselves must be responsible in a degree for the increased hemorrhage in such cases. Certainly some factor is present which we do not understand and I am free to state we are unable to control, for in my experience calcium lactate and the administration of foreign sera are alike powerless to stay this disastrous complication. Fortunately it is of rare occurrence and appears only in cases who have postponed operation to an indefinite extent. Rudolf and Cole[5] state that experimentally they are unable to observe any appreciable effect upon the coagulation time of the blood under the free exhibition of calcium lactate.

If operation has been decided upon the patient is prepared in the usual way followed by iodine disinfection of the skin after it has become dry. I prefer ether anesthesia to any other. It is important to have the patient in correct position on the table, which is accomplished by the use of a firm sand bag under the back, beneath the lower thoracic and not the lumbar vertebræ, which not only pushes the spine with liver and bile ducts forward, but also opens up the costal angle. Special attachments to operating tables for this purpose are less satisfactory than the use of the sand bag. A free incision is necessary if any surgical procedure is to be undertaken upon the common duct or in its neighborhood. The field of operation is to be thoroughly walled off with gauze and the gall-bladder first palpated and treated according to conditions found. In every instance in which I open the gall-bladder for stone I examine the cystic and common ducts for the presence of stones.

When, however, exploration of the common duct from above is not possible the problem may become a more difficult one. It is often no easy matter to identify the common duct as it may be so thick that it looks more like a cord than a duct. Just as, to reach the appendix, we use as guides the cecum, and the anterior longitudinal band to the base of the appendix, so to reach the common duct we may pass down the gall-bladder, to the cystic duct and thence to the common duct. If the duct cannot be differentiated from the portal vein hypodermic puncture

will determine whether we have the common duct or the portal vein with but few exceptions as already mentioned.

The common duct having been located and the presence of stone made certain, we must look for the quickest and safest method of its removal. If the gall-bladder has been opened it is at times possible to push the stone up into it and thus avoid opening the choledochus. This, however, is rarely the case, and is, of course, entirely out of the question if the stone be impacted.

When the stone is in the supraduodenal portion of the duct or can be carried there, the proper course of action is to make an incision over the stone, remove it and drain with a fish-tailed rubber tube, previously carrying the index finger through the foramen of Winslow by which the duct is lifted upward and made prominent. The stone having been removed, the duct is to be palpated for further obstruction. It is also my practice to carry the flexible olive-pointed gallstone explorer through the duct into the duodenum by way of the opening made for the extraction of the stone; I never feel satisfied unless I do this. Very frequently I bend the gallstone scoop, giving it the proper curve and pass it.

It is also advisable to explore the hepatic duct. When the opening of the hepatic duct is abnormally low it will be necessary to incise the common duct (rather the elongated cystic duct) the distance necessary to expose the opening.

When it is necessary to remove the gall-bladder and also to incise the common duct, the latter is easily located and identified by passing a probe through the amputated cystic duct into the common duct.

When the stone is in the retroduodenal or pancreatic portion of the duct every effort should be made to dislodge it into the supraduodenal portion, or failing this, either to scoop it out entirely or reducing it with the spoon of the scoop and removing it piecemeal, or push it through into the duodenum. Should its size or other conditions make this impossible it may be necessary to approach the stone by Kocher's retroduodenal method. This essentially consists in dividing the peritoneum along the right margin of the duodenum, carrying the loosened bowel up from its bed to expose the duct behind it. I have found this operation but rarely necessary and Mayo considers it as having a very small field of usefulness. Still more restricted are transduodenal choledochostomy or duodenocholedochostomy. These operations, which involve traversing the duodenum in order to approach the stone in the ampulla of Vater or the terminal portion of the common duct, I have fortunately been called upon to employ but once. I have never failed to dislodge a stone so located, either upward or downward, with the one exception. I consider the use of such an operation unjustifiable and dangerous except under the most unusual conditions—conditions which, in an extensive experience with gallstone surgery, I have, as I said, been obligated to do but once.

As Mayo so well says, "free drainage of the bile to the surface contributes more to the safety of the patient than any one other feature of the operation." Drainage is established by direct drainage of the common duct by a rubber tube, supplemented by a split-rubber or gauze drain to the site of the choledochostomy opening.

In suppurative cholangitis, which may follow infection of the gall-bladder, it becomes necessary to drain the common duct by a choledochotomy. Drainage of the gall-bladder alone in the presence of pus in the hepatic ducts and their radicles will not suffice. I have a patient under my care at the present time in which I made both a cholecystostomy and a choledochostomy introducing rubber drainage into both the gall-bladder and common duct. Immediately following the free drainage the chills and fever ceased and improvement at once took place.

In a badly infected gall-bladder with great enlargement of the liver in addition to cholecystostomy or cholecystectomy, as the case may be, I frequently drain the common duct. Lavage of the common and hepatic duct as recommended by Kehr may be of avail, yet I have never practised it.

The common-duct and gall-bladder drains are left in until they fall out, they having been sewed to the walls of the duct or gall-bladder opening by chromic catgut. When cicatricial contraction of the duct has occurred or is feared a T rubber tube is useful, its short arms projecting upward and downward into the duct, while the long arm is brought out of the incision for drainage. This permits the formation of a duct of sufficient lumen, much as occurs in the urethra when a catheter is used in the same manner after a perineal section for stricture. The accessory drains are removed in two or three days.

The treatment of the accompanying gall-bladder condition in common-duct cases varies. If the gall-bladder is diseased and useless a cholecystectomy plus common-duct drainage furnishes the operation of choice if sufficient of the cystic duct cannot be retained for drainage. If the gall-bladder be damaged beyond repair, choledochostomy plus the usual cholecystectomy is indicated.

A feature of interest in connection with cholecystic disease particularly, and stone in the common duct, is the frequent hardening of the head of the pancreas noted at operation with or without symptoms of pancreatic disturbance having been detected before the operation. This hardening may be interstitial pancreatitis or pancreatic lymphangitis. In many instances it is no doubt a true interstitial pancreatitis with deposits of fibrous tissue, but in others is is merely a lymphangitis pancreatica in which the swelling is due to edema and, perhaps, cellular infiltration and not to a true interstitial process. There are many small aggregations of lymph tissue about the head of the pancreas. It is also demonstrated that the lymph vessels along the course of the common duct communicate with the head of the pancreas. By this mechanism inflammation readily makes its way from the region of the gall-bladder to the pancreas, marking its path as it goes by means of the enlarged lymph glands commonly found along the course of the common duct in this condition. Pancreatic lymphangitis, as a rule, affects only the head of the organ, owing to the fact that the lymphatics of the head and those of the body are not intimately connected. This differs from the state of affairs found in the ordinary form of diffuse chronic interstitial pancreatitis in which the entire gland is involved and sclerotic. The treatment of pancreatic lymphangitis is comprised under the operations which are necessary to restore the biliary system, particularly the gall-bladder to a state of health. When the pancreas is much affected cholecystostomy will not suffice and cholecystenterostomy

must be done. This must be borne in mind since the pancreatic complication of gallstone disease is important and furnishes a good percentage of the failures of end results after operation. Recurrence of the inflammation in the gall-bladder after operation will again give rise to pancreatitis. Only a gall-bladder which has every appearance of being able to return speedily to normal should, therefore, be entrusted to the curative effects of a few weeks' drainage as afforded by simple cholecystostomy. The operation of choice is cholecystenterostomy to provide for permanent drainage. Such operations as choledochoduodenostomy I never perform except as a last resort.

Besides gallstones there are certain other conditions in which we are compelled to perform operations upon the common duct. Stricture due to old injuries or ulcerations, malignant growths of the duct or ampulla or old cicatrices in the duodenum blocking the ampulla may necessitate plastic operations upon the duct, resections or reimplantation. These belong to the rarities of surgery and must be met individually according to the exact nature of the case.

Of the after treatment in common-duct operations there is but little to say. The use of stimulation, saline by continuous enteroclysis, lavage of the stomach if there is persistent nausea or vomiting and restriction of food at first, follow the course pursued in all other grave abdominal operations.

Patients after common-duct operations who have been jaundiced for any length of time must be watched for hemorrhage. This is the most frequent cause of death and depends, not so much upon deficiencies in technique, as upon the patient's condition. Peritonitis practically never occurs and seldom uremia if the kidneys and the circulation are given the proper attention before and after operation.

The technique of common-duct operations has been highly perfected; if it should be possible to secure in some way an avoidance of the operative dangers due to jaundice the mortality would be reduced almost to that of any other gallstone operation.

Cholemia so closely resembles uremia that they are often confounded. In either event it is a toxemia and one is as bad as the other.

Myocarditis is so frequently present in gallstone disease that particular attention must be given to the heart and circulation. I defer operation much oftener on this account than because of the presence of jaundice.

Lymphatic Infection from Appendicitis Without Peritonitis.—A. E. Barker states that infection from a damaged vermiform appendix or epityphlon may run a very serious course without any obvious local or general peritonitis. He has seen several cases in which the infection had spread along the lymphatics of the organ and produced very grave conditions in the glands and areolar tissue behind the abdominal peritoneum without any local or general peritonitis.—*The Practitioner.*

PEDIATRIC MEMORANDA.

PRIMARY SPLENOHEPATOMEGALY IN BROTHER AND SISTER.

By HERMAN B. SHEFFIELD, M.D.,

NEW YORK.

The family history in the cases under consideration is negative. The parents had four children. The first child was born at full term and is now perfectly well. The same is true of the third child. The second child (see Figs. 1 and 3*) was apparently normal at birth. During infancy she suffered from gastrointestinal disease which left her delicate and subject to rachitis up to about two years of age. When about two and a half years old she was afflicted with bilateral submaxillary adenitis which terminated in suppuration, requiring free incision and drainage, and healed with difficulty. Her abdomen was always large. As she grew older the abdominal enlargement assumed greater dimen-

Fig. 1.

sions. Figure 1 shows the size of the spleen and liver when the child was about four years of age. When the girl came under my observation she was about eight and a half years old. The abdominal contour (see Fig. 3) resembled that of a pregnant woman approaching delivery. Palpation revealed a uniform hard mass occupying almost the entire abdominal cavity. The spleen could be mapped out spreading across the abdomen to the right inguinal region, taking a sort of semicircular course, while the liver extended downward and forward, almost filling the area left vacant by the spleen (see Fig. 3). Firm compression of the abdomen produced slight dyspnea, undoubtedly by indirect upward pressure upon the thoracic contents. Otherwise the child was free from discom-

*A few of the photographs reproduced in these Pediatric Memoranda have also been used for illustration in the author's "Modern Diagnosis and Treatment of Diseases of Children"; F. A. Davis Co., 1911.

fort. Her general appearance was excellent. She was quite stout, always happy, and, notwithstanding the heavy encumbrance, well able to roam about with celerity. Examination of the heart and kidneys proved negative. Careful examination of the blood at the New York Postgraduate Laboratory

Fig. 2.

disclosed the following: Hemoglobin, 75; red blood cells, 4,400,000; white blood cells, 17,500; polynuclears, 57½ per cent.; lymphocytes, 25 per cent.; large mononuclears, 15½ per cent.; transitionals, 2 per cent.; eosinophiles, 0.

The blood count thus eliminating any grave primary blood disease, there were only two other conditions to which the peculiar spleen and liver enlargements could have been attributed, viz., syphilis or amyloid degeneration. As at that time the Wassermann reaction was but little thought of and not within easy reach, the equally efficient therapeutic test was promptly resorted to instead. Antisyphilitic treatment was vigorously employed for two months without the slightest improvement in the child's condition, and, hence, given up. The history of marasmus, gastroenteritis, and the presence of suppurative foci all seemed to warrant the assumption that amyloid degeneration was here dealt with, and it was, therefore, decided to place the patient upon general tonic treatment and to await further developments. The patient never returned thereafter, but I have learned about six months ago, when the second child was brought to me, that she died suddenly two years later with symptoms of rupture of the spleen and intestines (profuse intestinal hemorrhage) and collapse.

Her three-year-old brother came under my observation last April. According to the mother he was apparently perfectly well at birth and remained so up to three years of age, though for some time previously the mother had noticed that his abdomen was unusually large. A few days before consulting me the child suffered from an attack of indigestion and was taken to Dr. J. Gutfreund for treatment. The doctor, recognizing the seriousness of the case in question, kindly referred it to me for diagnosis. As can readily be seen from the accompanying illustrations (Figs. 2 and 4) the topography of the liver and spleen resembles closely that of his sister (see Fig. 1). He was generally well developed and, like his sister, was free from any discomfort. Medicine having since the first case become enriched by two pathognomonic tests, *i.e.* the Wassermann and tuberculin reactions, my anticipation of soon lifting the veil of diagnostic mystery in the second as well as first case rose to the highest pitch of enthusiasm, and so much greater was my disappointment when I found the next day that the patient failed to respond to the von Pirquet test, and learned a few days later, from Dr. I. J. Levy, that the Wassermann reaction proved negative. Examination of the blood by Dr. N. Kruskal brought forth the following information: Hemoglobin, 65 per cent.; red blood cells, 3,100,000; white blood cells, 8,900; polymorphonuclears, 69.8 per cent.; lymphocytes, 24.4 per cent.; large mononuclears, 2.5 per cent.; eosinophiles, 2.8 per cent.; mast cells, 0.3 per cent.; myelocytes, 0 per cent.; no plasmodia.

While the blood picture differed considerably from that of his sister, yet it showed nothing tan-

Fig. 3.

gible to elucidate the diagnosis. Armed with all the scientific data obtained I took the patient over to our "grand old man," Dr. A. Jacobi, for consultation. After going over the case very carefully the doctor humorously remarked that it was one of the cases of large spleen and liver that every author

describes under a different name. He suggested the administration of large, rapidly increased, doses of arsenic until its full physiological effect had been obtained. The treatment was continued for about two months (reaching a dosage of 20 drops of Fowler's solution three times a day) without the

Fig. 4.

slightest beneficial influence upon the splenic and hepatic enlargement. I next referred the case to Dr. S. Flexner. He was unable to suggest any particular mode of treatment but very kindly called my attention to Drs. Brill and Libman's paper on two cases of "Primary Splenomegaly" (Gauchet) which bear a close resemblance to those under consideration.

Disappointed in the diagnosis as well as treatment, I directed the mother to go with the child to the country.

THE HEALED TUBERCULOUS LESION FROM A LIFE INSURANCE STANDPOINT.*

By GEORGE PARKER, M.D.,

PEORIA, ILL.,

MEDICAL DIRECTOR, PEORIA LIFE INSURANCE COMPANY.

The question of tuberculosis has been a serious one to insurance companies from their incipiency. The prevalence of this disease and the mortality resulting therefrom is the reason. The U. S. Census Reports give tuberculosis as a cause of more than 10 per cent. of the death rate, and about 150,000 persons die yearly in the United States from this disease. The occurrence of tuberculosis is, however, much more frequent than these figures show.

We gain our most comprehensive knowledge of it from post-mortem statistics. Naegli of Zurich found tuberculosis present in 90 per cent. of bodies examined. Burkhardt of Dresden found about the same percentage. Beitzke of Berlin, who examined 1100 bodies at the Charité, gave 58.2 per cent. in persons over fifteen years of age, but he omitted puckered scars of pleural adhesions at the apex and miniature fibrous nodules 2 or 3 millimeters in diameter found in the lungs and pleura. Naegli and others hold that these are tubercular. Prof. Harbitz of Norway says it is generally conceded that it is possible to demonstrate tuberculosis or traces of it in from 40 to 60 per cent. of cases. An anaylsis of 1,000 consecutive autopsies by Adami and McCrae gives a comprehensive idea of the incidence of the disease, its localization and its tendency to heal. They found evidences of past or present tuberculosis in 417 bodies, or 41.7 per cent.

(1) Healed lesions were found in 151 cases, or 36 per cent. Calcification and fibrosis with no caseous material or other evidence of latent or active disease. Average age, 46.2 years. Most frequent site: Lungs, 100 cases; thoracic glands, 45 cases; peribronchial, 38 cases.

(2) Latent, 93 cases. Show caseous or calcariocaseous foci; apparently quiescent and localized. Average age, 38.7 years. Most frequent site: Lungs.

(3) Early active tuberculosis, 22 cases. Evidence of disease becoming active from a latent site. Progress at time of death was inconsiderable. Death due to other causes. No average age given.

(4) Generalized, 43 cases. Diffuse infection of many organs. Average age, 19.3 years. Most frequent site: Lungs, 95 per cent.

(5) Pulmonary, 85 cases. Actual cases of phthisis, although it may terminally be in many other organs. Average age, 36.6 years.

(6) Tuberculosis of bones, 13 cases. Primarily in bones or joints, whatever be the final dissemination of it. In 8 cases lungs affected, in 3 cases pleura affected, in 6 cases thoracic glands involved. Average age, 26 years.

(7) Genitourinary, 10 cases. Tuberculosis manifest elsewhere in every case, but the genitourinary system the most advanced and important lesions. Average age, 31.9 years.

This short review teaches the following: (1) That the majority of all applicants applying for insurance have either active or healed or latent tuberculosis. (2) The post-mortem findings prove conclusively that tuberculosis can heal. (3) That the average age of the healed lesions in Adami and McCrae's 1,000 autopsies was 46.2 years and of latent cases 38.7 years, and that the average age of the active cases was less than that of the latent.

Bearing in mind these facts, let us pass to a discussion of the different forms of tuberculosis that will interest us from a life insurance standpoint.

I would make the following classification: 1. Pulmonary. 2. Bone and joint lesions. 3. Glandular. 4. Genitourinary. 5. Skin. 6. Fistula.

Under pulmonary, pleurisy, bronchitis, hoarseness, hemoptysis and such tuberculous vagaries as malaria, neurasthenia, overwork, indigestion, fever, anemia, subject to colds, etc., claim our attention. In deciding upon the acceptance of a case giving a history of pleurisy, the first question

*Read at the semi-annual meeting of the Medical Section of the American Life Convention at Pittsburgh, Pa., September 20, 1911.

that enters our mind is, Was it a tubercular pleurisy? The majority of all cases are tuberculous—witness the following five points in proof:

(1) Post-mortem evidence shows unmistakable proof and tubercles have even been found in acute cases thought to be rheumatic.

(2) Animal experimentation: Aschoff—68 per cent. of animals inoculated from cases of serous pleurisy succumb to tuberculosis. Le Damany—86 to 96 per cent.

(3) Cytodiagnosis. Mononuclear leucocytes predominate.

(4) Positive tuberculin reactions.

(5) Subsequent history. (a) H. I. Bowditch—Of 90 cases followed 30 years, 32 developed tuberculosis. (b) Hedges—130 cases, with effusion, followed 7 years, 40 per cent. became tuberculous. (*c*) R. C. Cabot—221 cases, followed 5 years, 117 developed or died from phthisis. (*d*) Hamman—562 cases; 167 of these, or 29.7 per cent., became tuberculous. We thus have definite proof of the tuberculous origin of pleurisy.

The next question of importance is that of a primary or secondary pleurisy. In exceptional cases it is primary, but it is most frequently an extension from a tuberculous lung or from peribronchial glands. That pleurisy heals is shown by the large number of pleural adhesions at autopsy. In considering a former pleurisy, we are asked to pass upon a case which is clinically well and may have been well for a number of years, but in view of the pathology it should be passed upon as an applicant having had tuberculosis of the lungs or peribronchial glands at the time of the pleurisy, unless it can be definitely proven otherwise. When a history of bronchitis or "cold on the chest," pneumonia, or hoarseness, is obtained, it must not be forgotten that these may be symptomatic of a pulmonary tuberculosis and suspicion must be aroused by (1) duration of the attack, (2) frequency of the attack, (3) family history, (4) weight, (5) other symptoms of tuberculosis.

A previous tuberculosis may come in on an examination blank as malaria, neurasthenia, overwork, indigestion, fever, anemia, grief, etc. These terms are of especial interest in light weight subjects.

The symptom of hemoptysis is closely linked with tuberculosis of the lung. It is diagnostic in a large number of cases, as shown by the following statistics: (1) Ware—Private practice. Of 386 cases, 324 showed pulmonary tuberculosis. (2) Franz Stricker—Prussian army. (*a*) Of 480 cases coming on without recognizable cause, 417 or 86 per cent. were tuberculous. (*b*) Of 213 cases coming on during military exercise, 75 were tuberculous. (*c*) Of 24 cases following trauma, 7 were positively tubercular and 6 very probably.

That hemoptysis can occur without other evidences of the disease is a positive clinical fact, and the following statistics show its frequency as an initial symptom: (1) Galbraith—*Practitioner*, 1907. Of 150 cases, 26 per cent. showed hemoptysis with no physical signs. (2) Coffman, *New York Medical Journal*, Feb. 2, 1907. Of 256 cases, hemoptysis 8 per cent. (3) Anders—Report at last International Congress for Tuberculosis. Of 3,010 cases an initial symptom in 9.1 per cent. As an early symptom, Anders states that of 2,084 cases, 1,439 of 68 per cent. showed hemoptysis in the first stage and early part of the second, or that of softening and ulceration.

The mortality of previous cases of hemoptysis is shown by the following: (1) Combined experience of Washington and National Life—69 cases: 27 deaths from consumption, 39.13 per cent.

(2) Actuarial Societies—Percentage of actual to expected deaths: Years 15-28, 136.6; 29-42, 110.6; 43-56, 105.2; 57-70, 84.8; 15-70, 107.7.

(3) Experience of a large old line company as given to me in a personal letter from the Medical Director: Of somewhat less than 500 cases—exact number not stated—insured between 1897 and 1908, there was a mortality of 14 points above the general average of the company on all its business for the same period. Cases accepted after at least a seven-year interval. A higher mortality was shown in the younger ages.

In regard to bone and joint tuberculosis, if we had in these lesions a primary localization to the bones and joints it would be much easier to handle them from an insurance standpoint, but pathological lesions teach us that in a great majority of cases it is a secondary lesion. Köenig is perhaps the greatest authority on this subject, and he states from his experience in post-mortem work that 79 per cent. of bone and joint tuberculosis is one of multiple foci. From our point of view, then, it is proper to consider bone and joint tuberculosis as a single manifestation of a multiple infection.

It has also been proven (Carless) that articular tuberculosis is more likely to be associated with pulmonary complications. That tuberculosis of bones and joints heals clinically is well known. Pathologically, the process may become encapsulated with fibrous tissue and eburnated bone, but Köenig has never observed complete disappearance of the tuberculous tissue. For this reason recurrences after clinical healing are frequent, especially after trauma. In fact, in no other disease is apparent healing more frequent than in tuberculosis of the bones and joints. The latent life or vitality of the tubercle bacillus in an encysted focus is well known, *e.g.* a woman at age 10 gave a history of a tubercular ankle, with apparent perfect healing, a free interval of 60 years, and then practically at the end of life, and after a slight injury all symptoms returned, and so rapidly that the foot had to be amputated, and in the lower end of the tibia an old tubercular focus with sequestra was found.

Köenig does not deny that healing with scar formation is possible, but if the tubercular process in the bone has produced a caseous sequestrum, this healing will always be apparent only, and recurrence is possible at any later interval after slight trauma. These facts make the ultimate prognosis in these cases unfavorable. Some authorities claim that in such cases there will be a recurrence within fifteen years, others before the age of 45. Billroth, after 16 years of observation, states that 27 per cent. of all cases of tuberculosis of joints die of tuberculosis. Köenig found a mortality in four years of 16 per cent. of 117 cases operated upon.

In 1903, 34 companies examined a number of applications where the applicant had suffered from hip joint disease, and the mortality was 28 points above the fair average risk. The percentage of actual to expected deaths, as given by the actuarial societies, in the case of hip joint disease, averages 127.9. The percentage was higher below 42 years of age, being 132.3.

Under the head of glandular tuberculosis we have to deal mostly with that of the cervical lymph glands. This localization of tuberculosis is most

common between the ages of 3 and 10 years, so that at the insurable age a number of years will have elapsed since the disease was active. Tuberculosis of the cervical glands differs from that of the bones and joints in that at first it is frequently the only tuberculous lesion in the body, being a direct infection from the mouth and throat. While local at first, however, it does not necessarily follow that it remains so, for it has been estimated that pulmonary and other tuberculous infections follow it in more than 25 per cent of the cases. As the course of tuberculous cervical glands is usually a prolonged one, it follows that the sooner they are removed by radical operation the less probable it is that multiple body foci will develop, and the more favorable is the future prognosis.

It is difficult to estimate the number of complete and permanent cures following radical operations. Dowd of New York, at the last Tuberculosis Congress, reported 275 cases. Among 54 cases observed for periods of from five to thirteen and a half years, 53, or 98 per cent., were apparently cured, in vigorous health, having either no palpable glands in the neck or only such small hard ones as were believed to be hyperplastic and not tuberculous. They were also free from evidences of tuberculosis in any other part of the body. A second group, 42 cases, followed 3 to 5 years—37 apparent cures, or 88 per cent. A third group, 87 cases, followed 1 to 3 years—83.8 per cent. apparent cures. A fourth group, 92 cases, followed less than a year, 85 per cent. cured. These statistics would indicate that those who have passed five years in good health since their operation need have little fear of serious recurrence.

Wohlgemuth claims 70 per cent. of cures after radical operation; Hobel, 68 per cent.; Van Norden, 62.4 per cent.—an average, then, of 65 per cent. in 309 cases. The prognosis after operation is more favorable in children than adults. It would seem from the above records that cases giving a history of early radical operation by a competent surgeon, before the infection became localized in other regions, as the lung, would give better results as to mortality than those that have healed without operation.

In discussing tuberculosis of the genitourinary system, I wish only to mention tuberculosis of the kidney and testicle. They are nearly always secondary to some other focus of infection. Cases of tuberculosis of the kidney in which nephrectomy has been done have no insurance value, but some of them recover and remain well for a number of years. Kröenlein has recorded health 18 years, and Israel 15 years, after nephrectomy for tuberculosis. Concerning tuberculosis of the testicle, apparent cures are recorded. Keyes in Annals of Surgery, June, 1907, says in 14 per cent. of cases. Relapse, however, takes place in the opposite testicle within a few years in 8 or 9 out of 10 cases. This large percentage of relapses would exclude the apparently healed lesions from an insurance standpoint.

In regard to skin tuberculosis: Here, as in other tuberculous lesions, systemic infection is liable to occur. In lupus, recurrences after apparent cure are frequent. Besnier states that 2 per cent. of his lupus patients died of consumption. Bender found that in 159 cases of cutaneous tuberculosis 62.3 per cent. showed present or past evidences of tuberculosis. Hereditary predisposition was noted in 33.3 per cent.

Fistula *in ano* is definitely known to be tuberculous in 40 to 50 per cent. of all cases. Bacilli have been demonstrated in the scrapings and in the tissue removed. Whether it is primary or secondary is the point of doubt. There is a much more general agreement as to the percentage of fistula occurring in the tuberculous, viz., 1 to 5 per cent. The fact that the presence of the bacilli in a fistula is so much more frequent than the occurrence of fistula in tubercular subjects makes it very probable that primary tuberculosis does occur in fistula. Steinthal states that 10 to 14 per cent. of those having tubercular fistula suffer from tuberculosis of the lungs. That tuberculous fistulæ remain cured after operation is certain, but the number in previous years is not so large. Tuttle says that a large percentage, if not a majority, of the cases of fistula operated upon in hospitals and treated by general surgeons are failures so far as cure is concerned. Of 2,196 cases less than 45 per cent. are claimed to have been cured.

One of our largest companies stated to me in a personal communication that in somewhat less than 500 cases insured between 1893 and 1908, they had a mortality of fourteen points above the general average of the company on all its business for the same period. I believe, however, that these results are especially unfavorable. If the fistula appears to be primary, and if the fistulous tract is thoroughly excised, and not simply slit open and curetted, it should heal permanently in almost all cases. C. U. Collins of Peoria gave me the records of 19 cases which he was able to trace. These were all cases in which the fistulous tract was excised, except two. They all reported no recurrence and that their present health was good. Eleven of the cases were operated upon more than four years ago. The series dates from 1896 to 1911.

At present there is a lack of statistical material from which to construct clear and definite rules for the acceptance of lives impaired by a previous tuberculosis. Some 42 companies are now engaged in preparing a combined statistical report which will include healed tuberculous lesions. The number of cases here will be large enough to be of value.

It is hard to know just how long healed tuberculous patients live, because it is almost impossible to follow them to the end of their lives. The most exact figures we now have are those coming from the well organized sanatoriums of the country. There is no doubt that the most favorable results in tuberculosis to-day are obtained from sanatorium treatment, and the end results in their incipient cases will give us a good idea as to the prognosis of healed tuberculosis.

N. D. Bardswell, Medical Superintendent of the King Edward VII Sanitarium, gives the condition in 1909 of 241 cases under treatment during the years 1901 to 1905. Of this number 62 were incipient cases, of which there were: Well, 46, or 74 per cent; alive, 1, or 1.6 per cent; dead, 11, or 17.6 per cent; lost sight of, 4, or 6.4 per cent. By well, he means so far as patient can tell he is in very good health and able to do normal daily work. Such a condition, however, is compatible with arrested tuberculosis. Bardswell, from his sanatorium experience, states that "pulmonary tuberculosis is a disease with a strong tendency to relapse, and the only true test of cure or arrest is the test of time."

Prof. Karl Pearsons worked out the mortality

experienced by the above 241 patients treated in Bardswell's Sanitarium. The following is a synopsis of the results in which the number of deaths expected has been calculated from the latest census tables after making proper allowance for age incidents:

	Actual No. of Deaths.	Expected No. of Deaths.
Incipient Cases—		
Males	8	1.9
Females	3	0.8
Moderately Advanced Cases—		
Males	24	3.4
Females	10	1.1
Far Advanced Cases—		
Males	46	1.1
Females	29	0.9
All Cases—		
Males	78	6.5
Females	42	6.2
Cases Apparently Cured or Arrested—		
Males	14	4.3
Females	4	1.2

From these figures you see the actual number of deaths was far greater than the expected number.

Lawrason Brown, at the last International Congress on Tuberculosis, presented some interesting figures from his experience at Saranac Lake. Taking the general population as a measure of what should be expected, he found for those discharged apparently cured that at the end of 5 years 94 per cent. of the expected are alive; at the end of 10 years 86 per cent. are alive; at the end of 15 years 89 per cent. are alive. The patients have a death rate at first twice, later about three, times that of the general population, a figure which is reduced after 8 or 10 years. In fact, from 11 to 20 years, inclusive, after discharge, the average death rate for these patients is 5.9 per 1,000, or only one-third to one-half of the expected death rate among the general population. The data, however, upon which this latter rate rests are too small to afford any considerable degree of approximation.

The Winyah Sanitarium, Asheville, N. C., gives the final results in 602 cases of pulmonary tuberculosis discharged 2 to 10 years ago, the results being concluded on December 31, 1906. Of these 171 were early or incipient. Of those cases discharged from the years 1897 to 1898, 14 cases were traced. Of these, 12 were living and in good health, the permanent result percentage being 85.7.

From 1899 to 1900, 37 traced, and all living and in good health, 100 per cent. From 1901-1902, 40 traced, 38 in good health, 88.4 per cent. From 1903-1904, 44 traced, 40 in good health, 88.9 per cent. A total of 132 cases traced, and of these 127 living and in good health, 91.4 per cent. The results for the moderately advanced and advanced cases are given in the Sanitarium Report for 1905 and 1906. The above results are based upon the patients' statements that they are in good health, and not upon critical examinations. Specific medication was used in all cases.

Dr. Carl von Ruck of the Winyah Sanitarium, in a personal communication to me, has applied his experience to the question of life insurance. He would accept:

(1) Early cases having had sanatorium and specific treatment combined that have recovered at least two years prior to applying for insurance, and that have the following conditions present: (*a*) They must have had no signs or symptoms for past two years, and none at present. (*b*) Normal weight. (*c*) An examination of the blood by a competent observer must still show the presence of antibodies, at least twice in amount of what is found in the serum of such who were not treated with specific remedies, *i.e.* specific agglutinins 1:100 and ambocepter 1:20.

(2) Early cases, after 3 to 5 years, in whom the blood shows only about one-half the degree of specific resistance as shown for enduring results after two years—and in whom the same conditions as in the first group were present.

(3) Early cases without blood examination after five years of apparent permanency.

(4) As fair risks cases who have apparently recovered from a further advanced stage, in which destructive changes were present, and which have obtained healing and cicatrization, the results of which may have led to retraction and fibrosis in one or both apices. In such cases he would limit the risk not to exceed two or three thousand dollars, and this only after an apparent permanency of from three to five years. He rates these as fair because there are not infrequently encapsulated caseous foci which may become active under the influence of non-tuberculous incidental inflammatory diseases of the air passages.

He closes his communication by saying: "In complete recovery, as shown in early stage cases, by absence of all physical signs, and after two years, with good nutrition and continued specific resistance, I really believe the case would be unconditionally a good risk, for you can then eliminate the probability of an outbreak of a possibly overlooked latent focus and the prospect of a loss from phthisis at a later period."

Dr. Lawrason Brown, resident physician at the Adirondack Cottage Sanatorium, Saranac Lake, has also expressed his views to me. His experience leads him to believe that when a man once has tuberculosis he is never in the same condition that he was before. He thinks some rates might be made for patients who have fully recovered from tuberculosis and have been well, living under the ordinary conditions of life for a period of five years. He does not believe that the tuberculin tests, agglutination, etc., will prove of any value whatsoever in determining the advisability of granting insurance. The opsonic index taken before and after exercise may prove of some value. It may be sufficient to know what a person's temperature is before and after the exercise test.

He is of the opinion that it is a foolish thing for companies to refuse insurance to a man who has had tuberculosis and lives in a good climate, while they accept applicants who live in ordinary climates which may or may not be suitable. His experience teaches him that the patients who recover and live in the so-called health resorts remain well, while those who return home are more or less uncertain. He thinks the prognosis in tuberculosis is notoriously uncertain and that time is the only true test as to the efficiency of permanent arrest. He believes in the cases permanently arrested the patients must take the greatest care of themselves, and for this reason he thinks that a patient makes a much better arrest who is stolid and careful than one who is quick, impulsive, or neurotic to an extreme degree.

F. M. Pottenger, Monrovia, Cal., expressed the following views at the last International Con-

gress for Tuberculosis: (1) Patients may regain their weight and still have active tuberculosis. (2) Absence of all symptoms with signs of a healed process on auscultation affords strong presumptive evidence of cure, but is not absolute. (3) The only reliable test is the tuberculin test. If there are no symptoms or physical signs, and no reaction to ten mg. of tuberculin, one is safe in calling the case cured. If case has been treated with tuberculin, the test is not reliable until six months has elapsed since the last injection. (4) All cured patients should be careful not to subject themselves to any unnecessary strain.

Thus we have the views from three of the leading sanatoriums of America in different parts of the country,—views which represent the best thought of men who have made a special study of the disease and watched their cases closely.

There is no doubt that the advent of up-to-date sanatorium treatment, tuberculin, Bier's treatment, Beck's bismuth paste, and the increasing skill in diagnosis and surgery, will increase the number of cures and make them more permanent; but past tuberculosis at present still falls in the class of substandard risks and must be dealt with accordingly. One of our weakest points, and the one which increases our mortality most, is the incompetent examination of the applicant. This is conclusively proven when we stop to think that tuberculosis costs American Life Insurance Companies nearly $50,000,000 each year. This also means that present day examination requirements are not sufficiently exacting. The substandard risk can be handled with more impunity than the average applicant. He will submit to a stricter examination and more inconvenience than the ordinary applicant.

If such present ultra-insurance methods as tuberculin and the opsonic index tests be used—as well as *x*-ray chest examinations—we may then be able to accept these cases as standard risks. The value of an *x*-ray photograph in a case of previous blood spitting or pleurisy would be of inestimable value, and the time is not far distant when the applicant would not travel far to find a competent radiographer. I present a number of plates taken by Geo. H. Weber of Peoria, showing that it is possible by this method to detect very early changes in the lungs. Even small tubercles can be seen. Larger areas of consolidation are also visible, as well as cavity formation. Healed calcified areas stand out very prominently. It is better to take the radiographs stereoptically, as in single plates shadows are apt to be superimposed. There is no question but what the radiograph shows changes that cannot be detected by physical examination. Without the use of special tests and investigations we must still follow the course we have been pursuing.

In deciding upon the acceptance of an applicant with a past tuberculous history, these points of importance are to be considered: (1) The length of time since the lesion was active. This will vary from 5 to 15 or more years. (2) Freedom from all tuberculous symptoms during this time, with the usual capacity for work. (3) Best weight—weight at time the lesion was active and present weight. (4) Family history and personal association with tuberculosis since that time. (5) Occupation and station in life. (6) Age. (7) Temperature test—evening temperature, temperature after exercise. (8) Pulse rate. (9) Present condition of health as determined by a careful physical examination.

THE ROLE AND METHODS OF PSYCHOTHERAPY IN THE CARE OF THE PSYCHASTHENIA PREDISPOSING TO INEBRIETY.

THE FUNCTIONS OF THE GENERAL PRACTITIONER APART FROM THOSE OF THE SPECIALIST AND THE SANATORIUM.*

By TOM A. WILLIAMS, M.B., C.M. (Edin.),

WASHINGTON, D. C.,

CORRESPONDING MEMBER OF THE NEUROLOGICAL AND THE PSYCHOLOGICAL SOCIETIES OF PARIS; MEMBER OF THE AMERICAN PSYCHOPATHOLOGICAL ASSOCIATION; NEUROLOGIST TO THE EPIPHANY FREE DISPENSARY.

When a person is sodden with alcohol or other drug, and has been so for several months, treatment in a sanatorium is, I believe, more economical, efficacious and rapid than is treatment in his own home. No more need be said here of treatment in the sanatorium. When a patient is in a state of profound mental and physical depression or excitement from chronic imbibition of narcotics, and there is a suspicion of further physical or mental derangement, the need of exact differentiation may demand the services of a neurological specialist. I need not expand this admitted principle. Like the foregoing, it is well known. In neither case would a general practitioner assume responsibility. But a diagnosis is seldom long delayed; and stay in a sanatorium is comparatively short. In each case, however, the after-care of the patient may be long. In the vast majority of cases it should be in the hands of a general practitioner.

It is a pity that few are yet equipped to help the poor sick souls who have taken to drink. If they are not helped, the majority will relapse; and, as a very little help suffices in most cases, it behooves practitioners to become acquainted with the principles with which to guide such patients in their struggles. A few of these I shall try to set down.

The Pathogenesis of Inebriety.—Drunkenness is not an individual disease. Not even are all addicts neurotics; though they generally are.[1] Those who drink from habit, convention, or conviction and could cease if they wished are not subjects for medical care, and do not concern us here. Of the remainder, the largest number, I believe, are persons suffering from feelings of inadequacy for the duties they have to perform. They are "psyschasthenics" potentially, if not as regards active symtoms.[2] Like every one else, these persons have ups and downs; but the downs are often prolonged. The inconvenience, discomfort, and even suffering of their depressions make them seek relief. The means they take depends upon circumstances. If the environment has provided ready access to alcohol, this means may be used to suppress their painful feelings. If, during sickness, opiates have been administered too long to such a person, he may become addicted to their use in order to obtain the exhilaration which again makes life seem worth living. The temporary removal of cravings is only one step toward that which these persons require. It is our duty to ascertain the cause of their addiction, and to remove that. The psychasthenia which is at the root of it must be met.

Of the physical factors in the causation of this I shall not speak at length. Their removal is comprised in the resources of medical art. The most conspicuous part in the physical treatment should

*Read at a meeting of the Mississippi Valley Medical Association, October 17-19, 1911.

be played by the physiological measures concerned in diet, bathing, exercise, and rest.[3] Second in importance to these are perhaps the measures concerned with the internal secretions, in which unfortunately our knowledge is at present deficient.

Psychic Factors in the Treatment of Psychasthenia.—But it is psychic measures which are our mainstay in the reconstitution of these patients' powers. It is true that in very severe cases the giving way to their desolating feeling of inadequacy and obsessions and fears is almost imperative But these cases are less common than those in which the giving way to the feeling has become a habit which has occurred from lack of the proper training in inhibition which most normal people acquire accidentally, perhaps, by force of circumstance. In these patients the physician must do by deliberate intention what has failed to be effected fortuitously. The patient must be reeducated.

The first step must consist in the physician's conveying to the patient the fact that he understands* his mental constitution and demonstrating the nature of his defect and that he is in need of reëducation for its removal. This task is easy to a physician who is trained in psychopathology. But the average man at present would be likely to confuse the patient, and make him sceptical of the powers of medical science in his case. Hence, it is better if the psychodiagnosis and plan of treatment are both made by a pyschopathological expert in consultation. From him the general practitioner ascertains the pathogenesis and the principles and means to be used in reeducating the patient toward the removal of his psychasthenia.[4]

While, therapeutically speaking, every man's impulse or craving to drink or debauch can be destroyed by denudation and attrition, yet, sociologically speaking, it is not always worth while, and the effort needed may be more fruitfully expended otherwise. But in a majority of psychasthenics, when they are otherwise estimable, a reeducation of their perverse craving is both practicable and profitable in the making of contentment out of unhappiness and usefulness to others from a burden to friends.

The Principles (1).—Acquisition of tolerance of the feeling of insufficiency through not being at one's best and highest mental level. (2) Acquirement of the poise which does not hurry, fuss, and bustle in face of heavy work or responsibilities.

A true philosophy of life is here an enormous help, a sentiment of the relative littleness of one's own task and importance. The dread of failure must be eliminated by minimizing to the patient the consequences of temporary lapses into discouragement and inadequacy. He must be shown their inevitableness unless mental gymnastics have strengthened him beyond them.

Isolation is usually detrimental rather than beneficial in psychasthenics. Forced feeding, electricity, baths, massage demand efforts which the physician had better utilize in real therapeutics instead of these shams of helps. These preliminary objects are attained by instruction, persuasion, knowledge. The patient must be taught himself, his psychology, his limitations. His expectations regarding his powers must be corrected. He must know himself biologically, *i.e.* understand his place in the cosmos, his mental machinery as a function of ontogenetic and phylogenetic adaptation.

The relics of false notions, the atavisms of metaphysics and superstition must be eliminated from his creed of life. In other words, he must acquire the rudiments of functional and genetic psychophysiology as we know it to-day.

But all this will often fail to remove suffering or develop self-control, unless further assistance is given in application of methods to overcome vicious mental habits. Fear, worry, anxiety, doubt, moral cowardice, craving or uplift are not removed in all cases by mere philosophical conviction. Practical exercises are required. Thus, the knowledge that a sniffing tic arose from a former crust in the nose would not help a patient to abolish the desire to sniff unless, by organized and systematic exercises to control the desire by inhibiting the act, he put himself to succeed. So a knowledge of why he craves alcohol does not remove the craving. Exercises in control are needed to abolish the psychic state of which the craving is only one expression.

The principle of this is the same as in that of the psychomotor discipline which is used in curing tic. It consists in the frequent concentration for short periods upon simple, easy tasks, which are made more complex and difficult gradually. It is merely a mental and moral gymnastic.

It is in the choosing and adapting of these exercises to the individual that the physician will need judgment. But far more exacting is the maintaining of the patient's attention strictly upon the task. It is so easy in itself that automatic performance is a constant temptation. This is worse than useless of course; but it is most difficult to obviate. The work is really a pathopedagogy.

The Method.—The following exercises give some idea of the method to use. They are in the main taken from the work of Vittoz, who has been very successful in teaching self-control to psychasthenics who have lost it. The exercises can be modified and supplemented at the wish of the physician. But the important matter is not the exercises themselves, but the way in which they are done. The greatest care must be taken that the maximum of attention is paid by the patient to the particular exercise he is doing, in order that the power of concentration may be practised. When this is attained a powerful suggestion is furnished to counteract the suggestion of failure which is dominant in the mental attitude of these patients, who have so often succumbed to the play of depressed feeling. This, however, is only a subsidiary factor; for the real essential is the actually increased power of self-control.

EXERCISES IN CONCENTRATION FOR OBTAINING MENTAL CONTROL.

Each must be done with the greatest intentness and exclusive attention while quiet and alone. About ten minutes every two hours during the day should be devoted to the work.

First Day—(1) For concentration in the con-

*It is taken for granted that the various psychoanalytical methods for discovering the genesis of psychological perturbations are at the clinician's command, and that he understands the significance of the ideogenetic affects which so often determine conduct unrealized by the patient. The mechanism of some of these is discussed by the author in "Notion and Emotion in Traumatic Neurosis," *Journal of Abnormal Psychology*, June, 1910. "Genesis of Hysterical Status in Childhood," etc., MEDICAL RECORD, August 6, 1910. Also by Morton Prince, *Journal of Abnormal Psychology*, and by Freud and his followers, whose methods and data are of great value except when they are vitiated by fantastical interpretations or rendered misleading by observations colored beyond reliability through a forced comformity to a cherished theory as to pathogenesis.

trol of movement: Bend the left arm very slowly with full consciousness of each movement and by willing the act very clearly. (2) For concentration upon impressions of touch: Take in hand a marble, eyes closed. Think of it; (a) size, (b) contour, (c) smoothness, (d) consistency; each separately. (3) For concentration upon impressions of hearing: Listen to the tick of a watch for thirty seconds as to—(a) loudness, (b) musical note, (c) regularity, (d) grouping of sound into series. (4) For concentration upon impressions of sight: Look at a marble, thinking of the various properties ascertained by touch, as well as its color.

Second Day—(1) Bend the right arm very slowly with full consciousness of each movement and by willing the act very clearly. (2) the same as (2) above, substituting a cotton reel for the marble. (3) Listen to the street car as to the same qualities. (4) as (4) above, substituting a cotton reel for the marble.

Third Day—(1) Same as (1 above) with left leg. (2) Same as (2) above with a pencil. (3) Repeat (3) above in imagination. (4) A stating as to the preceding character as well as its esthetic.

Fourth Day—(1) Same as (1) above with right leg. (2) The same as (2 above) with a small bottle. (3) Repeat in imagination. (4) Same as (4) above, substituting a picture.

Fifth Day—(1) Bending the trunk forward. (2) Repeat (2) without the objects. (3) Repeat (3) in imagination. (4) Repeat (4) from memory.

Sixth Day—(1) Bending the trunk to the right. (2) Repeat (2) without the object. (3) Repeat (3) in imagination. (4) Repeat (4) from memory.

Seventh Day—(1) Bend trunk to the left. (2) Repeat (2) without the objects. (3) Repeat (3) in imagination. (4) Repeat (4) from memory.

When perfected, each exercise can be done in imagination by intense concentration.

From the indifferent matter which forms the exercises, the patient proceeds to attempt control in matters of the daily life. The physician first selects matters into which the least feeling enters, and gradually imposes more and more difficult exercises, until finally temptations are deliberately chosen, in order that practice in their conquest may be given.* Until this stage is reached, the patient must be protected from temptations at least during the period when his mental level falls.

To do this, I have found it sufficient that the patient be imbued with the need of immediately communicating with his physician when the psychasthenic phase occurs. It is then usually easy to carry him through this until he recovers from his depression. He is only longing for moral support; and his lack of will at these times is satisfactorily compensated by that of the physician, by whom his occupation during the next few hours should be directed. It is not necessary that the physician do this in person; but he must know, by a study of his patient, what is most suitable under the conditions of each case.* The patient usually leaves buoyed up with the will to undertake what he has been directed to perform; and, in the performance, his aboulia and feeling of insufficiency generally vanish quickly.

*Of course the method here outlined is only one of the applications by which can be carried out the principle of invoking the attention toward concentrating the mind in a desired direction. Others, each successful in certain situations, are: (1) A reorientation of ideas, as by religious conversion; (2) the learning to ignore one's physical sensations, as by adopting Christian Science or other convenient nepenthe; (3) the emotional appeal of a great affection or the desire for respect of others; (4) the leaning upon another will, as in hypnosis or other so-called suggestive therapeusis. Of these methods, the second and fourth are obviously undesirable, while the availability of the others is not at therapeutic command.

THE RECOGNITION AND TREATMENT OF GONORRHEAL CERVICITIS AND ENDOMETRITIS.†

BY WALTER T. DANNREUTHER, M.D.

NEW YORK.

IN gonorrheal infections of the cervical canal and endometrium the diagnostic difficulties, tendency to chronicity, danger of complications, and resistance to treatment are far greater than in gonococcal invasions of the female urethra. Notwithstanding the common acceptation that the urethra is the most frequent site of primary infection, personal experience has demonstrated that where either the urethra or uterus alone is affected the latter is diseased three times as often as the former. These conclusions are deduced from microscopical examination of the specimens obtained from every gynecological case encountered in dispensary, hospital, and private practice during the past six years. Another surprising result of these routine microscopical examinations is the frequency with which gonococci were discovered in individuals in whom their presence was unsuspected and would otherwise have been overlooked. Apparently the gonococcus does not discriminate between the lowly and wealthy, young and aged, or dissolute and respectable. Gram negative, intracellular gonococci were disclosed in the uteri of little girls, young women before marriage, married women, and spinsters past the menopause. The method of infection may be traced to a variety of sources. These may be conveniently divided into: 1. Direct, (a) immediate infection by coitus with a male suffering from an active gonorrhea, or (b) delayed transmission by intercourse with a male with a previous acute gonorrhea, existing as an uncured gonorrhea, or recrudescence of a latent posterior urethritis or prostatitis, due either to carelessness or to neglect on the part of the physician. 2. Indirect, (a) unclean and infected towels and bed linen, (b) toilet seats, or (c) dirty and borrowed fountain syringes or douche nozzles. Those infections contracted immediately by a single coitus require no explanation. It frequently happens, however, that a married woman will successfully resist gonococcal invasion for some time and later become infected. Assuming that the husband has a chronic gonorrheal urethritis or prostatitis, this may be due to a renewed activity of the quiescent micro-

*The advantage of the physician seeing the patient is that he can then detect any metabolic or other physical disturbance which may be the source of the patient's craving, in which case physical measures supplant psychiatric.

†Read before the Jersey City Hospital Alumni Association, Jersey City, N. J., September 18, 1911.

organisms or to the lowered resistance of the patient herself, incident to the first puerperium, pelvic circulatory disturbances, etc. Whilst many cases of chronic gonorrhea exist in men because of their own ignorance or neglect, many others are undoubtedly due to the errors or carelessness of their physicians. Thus, the physician who informs his patient that his gonorrhea is cured, without proving the statement by careful and thorough clinical and microscopical examinations, fails to fulfill his duties. Unfortunately there are practitioners who assure their patients that a morning drop is insignificant and will cease spontaneously, or the physician may neglect to strip the prostate and seminal vesicles and submit the secretion to microscopic examination.

Gonorrhea is undoubtedly acquired by innocent women at times by means of soiled linen which has been in contact with the genitals of another infected individual. Neither is infection from a toilet seat exclusively a theoretical possibility. A number of cases have been observed recently in which the infection was undoubtedly transmitted by the seat of a public toilet which had been smeared with the discharge or menstrual blood of a gonorrheic. The logical remedy for this evil is the removal of a V-shaped section from the front of the seat, as is now customary in the toilets of modern department stores and hotels. A woman should be most careful regarding the nozzle of her douche apparatus. It should always be thoroughly cleansed after using and put away so that it cannot be temporarily appropriated by visitors and friends. The physician is accustomed to regard the source of a patient's gonorrheal infection as a matter of indifference, although this is of great importance, if innocent women are to be protected.

The positive diagnosis of a gonorrheal infection depends upon the microscope. The term "leucorrhea," as commonly used, may indicate anything from a slight increase in the normal mucoid secretion to a virulent pyogenic process, and has no significance as a symptom, because of the variety of conditions from which it may arise. When a patient has a vaginal discharge its true character and source must be ascertained, if it is to be of any service as a diagnostic aid. The annoyance of a leucorrhea may be relieved by the use of suitable washes and douches, yet without removing or destroying the origin of the discharge, little will be gained other than a temporary decrease in its quantity. Although the history and symptoms in a given case may be strongly suggestive of an acute gonorrheal infection, the acute cases are not the ones most frequently observed. Even here the diagnosis must always be verified by the microscope, since much the same condition may be produced by the streptococcus, staphylococcus, or a mixed infection. Many women, particularly those newly married, regard a vaginal discharge without other manifestations of trouble as a matter of no consequence and unworthy of medical attention. Acute urethral symptoms will usually cause the patient to consult her physician immediately, but these cases are in the minority, and he is therefore seldom afforded the opportunity of instituting treatment early.* A diagnosis of gonorrheal cervicitis and endometritis should be based upon (1) the history, (2) symptoms, (3) appearance of the cervix and cervical discharge, and (4) microscopical examination of the discharge.

*The Recognition of Gonorrheal Urethritis and Cystitis in Women. MEDICAL RECORD, February 2, 1911.

The history may or may not suggest the probability of infection. Many women will not hesitate to evade or deny the issue, if possible. When the patient acknowledges a previous coitus, followed perhaps by acute symptoms, it may be considered of importance, but the physician's judgment should not be influenced by a negative history.

Since gonorrhea may exist in women as an acute, subacute, or chronic condition, the intensity of the symptoms will vary accordingly. The most prominent sign in all cases is a sudden or gradual increase in vaginal moisture. This may amount to a profuse discharge of thick greenish or yellowish pus, to a constant white discharge, or to what appears to be but an indefinite slight excess of vaginal mucus. Many cases being subacute or chronic primarily, without a preexisting acute process and causing no discomfort, may escape the notice of the patient until accidentally discovered by the physician. A persistent mucopurulent discharge may excoriate the vulva, giving rise to irritation, itching, and a mild dermatitis. Dyspareunia occurs occasionally. The burning on urination in early gonorrheal cases is not usually due to urethral irritation, as in men, but is more often the result of the urine dribbling over the excoriated mucous membrane of the vulva. The peracute cases may be accompanied by severe pelvic discomfort and lumbosacral pain, but these are infrequent. Reflex systemic disturbances are not uncommon manifestations of chronic endocervicitis. Abortion or sterility often follows.

The appearance of the cervix and external os may indicate an infection. In acute cases the cervix may be so diseased as to resemble a cauliflower, covered with offensive pus. In those less acute the mucosa may be swollen, everted, and hypersecreting. In chronic cases erosions of the surface about the external os and distended Nabothian glands are usually found. Hemorrhagic oozing follows slight traumatism.

Irrespective of the presence or absence of a suggestive history, the symptoms and physical signs, the diagnosis of a gonorrheal infection can and must be made by microscopic examinations of specimens of the mucus or discharge. Specimens are best obtained in a little sterile cotton, wound on an applicator. One is taken from within the meatus urinarius, one from the vaginal orifice, and one from the cervical canal. The urethral specimen has been discussed in the paper previously mentioned and will be disregarded here. Occasionally the physician will be mystified by the presence of gonococci in the specimen taken from the vaginal orifice, when none can be detected in the cervical specimen. This is due to gonococcal invasion of Bartholin's glands without infection of the endometrium. Identification of the gonococcus is often difficult and the services of a trained and competent pathologist should be sought whenever available. A single examination may determine the presence of the microorganisms, but should never be deemed sufficient evidence when negative. To promote glandular secretion stimulation by means of the negative pole of the galvanic current applied within the cervical canal, as advocated by Goelet, will prove efficient. The physician should be satisfied only after repeated failures to demonstrate gonococci. The pathological report should mention all the features of the specimen.

Infections of the adnexa and peritoneum are frequent complications of the uterine disease. Not

only may the patient's pelvic organs be partially or completely destroyed, but even her life may be jeopardized. Efforts must therefore be made to prevent extension of the uterine infection. These conditions will be considered separately in a future paper.

The acute cases must be confined to bed and treated like all other pyogenic infections. The emunctories should be kept active and the diet limited. The vagina should be frequently cleansed with large quantities of hot water. Saline solution, boric acid, and weak iodine solutions are suitable for this purpose. The nozzle of the irrigator or syringe should have a single aperture and project a straight, forcible stream. If the mucous membrane surrounding the introitus is gently pinched around the neck of the nozzle, the vagina will be completely distended and satisfactorily flushed. When fully ballooned, the pressure may be relaxed and the fluid permitted to escape. These maneuvers should be repeated until three or four quarts have been used. The ordinary female douche nozzle, with several lateral pin-point holes, is of no practical value, as it fails to wash out the retained pus and secretions from the folds and wrinkles in the vaginal mucous membrane. Intrauterine measures and pelvic operative intervention are absolutely contraindicated, particularly routine intrauterine douching, curettage, and hysterectomy. When the acute process has subsided the case may be considered subacute or chronic.

The subacute cases are more conveniently treated in the physician's office. The cervix is softened and dilated by means of Goelet's uterine electrodes and the galvanic current. When sufficiently dilated the uterine cavity should be flushed through an intrauterine irrigator with a hot watery solution of iodine, one dram of the tincture to a quart of water, or silver nitrate, 1-5000. As the condition improves daily intrauterine injections of iodized phenol (equal parts of tincture of iodine and carbolic acid) or silver nitrate, 1 per cent., are substituted. For this purpose an instrument similar to the Ultzmann syringe is selected, except that the nozzle is longer and pliable and has several lateral holes near the tip. After filling the syringe this is wrapped with cotton and introduced into the uterine cavity. The fluid is injected into the cotton and the syringe withdrawn, leaving the saturated cotton within the cavity and protruding from the internal os. An iodine-glycerin tampon (one dram to four ounces) is inserted to favor depletion and drainage; this the patient is instructed to remove the next morning. The medicated cotton within the uterus is extracted at the next office visit.

In chronic cases diseased Nabothian glands must be punctured, evacuated, and sterilized. This is also an important preliminary to all plastic cervical operations, often unrecognized or neglected. The opened glands and erosions about the os are touched with pure tincture of iodine. The intrauterine irrigations and injections, advised for subacute conditions, given three times a week, may also prove useful in chronic cases. Curettage of the uterus is a much abused and misapplied operation in gonorrheal cases and will seldom effect a cure unaided. To effect a complete cure, it should be followed by swabbing with tincture of iodine and appropriate after-treatment. When curetting for gonorrheal endometritis, the cavity should be curetted with a semisharp and not a sharp instrument. This will express the glandular contents, but will not strip off sections of endometrium indiscriminately. The internal os and cervical canal, however, should be thoroughly scraped with a slender, sharp curette. The freshened surface is then flushed and generously painted with iodine.

It must be ever remembered that absence of discharge is no criterion or evidence of cure, any more than it is in the male under the same circumstances. The patient should not be dismissed until a number of consecutive specimens have all proven negative.

The efficiency of iodine as a germicide was bacteriologically demonstrated by Sternberg in 1883, who found that a 1-4000 solution completely destroyed gonococci in thirty seconds. These findings have been recently substantiated in the laboratory by Post and Nicoll, and amply verified by clinical experience. The writer first reported the results of his experience with iodine as an antiseptic and germicide in surgical, obstetrical, and gynecological practice in 1907. The results obtained in gonorrheal infections in women from the treatment herein outlined have been extremely satisfactory and encouraging. My friend, Dr. Terry M. Townsend, informs me that iodine has proven an utter failure in the treatment of gonorrhea in the male. Why this discrepancy between the effects in gynecological and genitourinary practice should exist I am unable to explain. Suffice it to say that the laboratory observations are fully confirmed by the rapidity with which gonococci are destroyed by this agent in the female.

Gonorrheal cases require as much, if not more, study and attention to detail as do other gynecological conditions. It is a serious error to prescribe a douche and dismiss a patient without determining the source of the trouble and the absence of a specific infection. The streptococcus and staphylococcus are only slightly less harmful than the gonococcus.

It may not be amiss to remind the reader that the subject of gonorrheal urethritis in women has been entirely omitted in the present paper, it having been considered in a previous one.

2030 Broadway.

USE OF IPECAC TO ABORT TYPHOID FEVER.

By WM. LAWRENCE FRAZIER, M.D.,

MOUNTAIN HOME, IDAHO.

Several recent reports have clearly shown the efficiency of ipecac in the treatment of tropical dysentery, when the drug is properly employed. I took the ipecac treatment for tropical dysentery one year ago with results that were entirely satisfactory, and after a number of other proposed treatments had proven non-effective in my case. It appeared to me that it should be equally as efficient in typhoid fever. The following shows the results in six cases treated.

Case I.—Woman 44 years of age. She was seen first on the third day after becoming confined to her bed; the case was diagnosed as typhoid fever on the sixth day of her illness, Widal test being positive. At 8 P. M. of the sixth day she was given fifteen minims of tincture of opium; thirty minutes later she was given thirty grains of pulverized ipecac in salol-coated capsules; the room was made dark and she was required to lie on her right side for two hours, so that the capsules might pass out of the stomach as quickly as possible. In this way vomiting was prevented by getting the ipecac past the stom-

ach without coming in contact with the stomach wall. On the seventh, eighth and ninth days ipecac was given in the same manner, the dose being decreased five grains each day; on the ninth day the dose being ten grains. On the tenth, eleventh and twelfth days the dose was ten grains each day. The highest temperature recorded was 103.8° on the seventh day. The highest recorded on the eighth day was 103.2°. The highest on the ninth day was 99.6°. There was no elevation of temperature after the ninth day. (Note that the ninth day of her illness was the fourth day she was given ipecac.)

Case II.—Man 32 years of age. He was confined to his bed on the third day of his illness. The diagnosis of typhoid fever was declared positive on the sixth day. On the same day ipecac treatment was begun and carried out as in Case I., except that the ipecac was continued until the fourteenth day. The highest temperature recorded was 102.5°, which was on the sixth and also on the seventh day. On the eighth day the highest temperature was 102.3°; on the ninth day, 102.1°; on the tenth day, 102°; on the eleventh, 100.7°; on the twelfth day, 100.6°; there was no fever recorded after the twelfth day, which was the seventh day ipecac was administered.

Case III.—Boy 12 years of age. Five days after he became confined to his bed the ipecac treatment was begun. The treatment was the same as in previous cases except that only five drops of the tincture of opium were given and the ipecac was begun in fifteen grain doses and gradually decreased to five grains and continued in five grain doses until the thirteenth day. On the seventh day his temperature was 103.8°, which was the highest temperature recorded. On the morning of the ninth day he had no fever, this being the fourth day ipecac was given.

Case IV.—Boy 6 years of age. The treatment in this case was a little different from that of the previous cases. Tincture of opium was left out of the treatment and instead of giving one dose of ipecac at night the dose was divided and eight grains were given at night and eight grains in the morning. This dosage was given without reducing the dose from the fifth until the eleventh day. His temperature on the fifth day reached 104.2°. On the sixth day it reached 104.5°. On the seventh day the maximum was 102.4°. On the eighth day at 2 P. M., 99.5°. On the same day, at 9 P. M. it was 98.1°. He had no more fever and the ipecac was given once a day from the twelfth until the fifteenth day in eight grain doses. It will be noticed that in this case the ipecac was begun on the fifth day and that there was no elevation of temperature after the eighth day.

Case V.—Woman 27 years of age. The ipecac treatment was begun on the seventh day that she was confined to her bed. In this case the opium was not given. As in Case IV., the ipecac was given morning and evening; in this case, in ten grain doses from the seventh until the thirteenth day; on the fourteenth, fifteenth and sixteenth days it was given in ten grain doses once each day. The highest temperature recorded was on the sixth day, when it was 104.6°; on the seventh day it was 104.4°; on the eighth day, 104.4°; on the ninth day, 103.9°; on the tenth day, at 8 A. M., 99.1°; at 9 P. M., 97.4°. It will be noticed that in this case the temperature became normal in about seventy-two hours after the ipecac treatment was begun.

Case VI.—Man 28 years of age. The administration of ipecac was begun on the fourth day of his confinement to bed, which was the seventh day of his illness. Ipecac was administered in twelve-grain doses every six hours. At the end of sixty hours he had no fever; ten grains were then given twice each day for a period of three days. The highest temperature reached was on the fourth day of his confinement to bed, when it was 104.3°. On the fifth day it reached 103.6°; on the sixth at 9 A. M., 101.2°, and at 9 P. M., 99.3°. On the seventh day the temperature was normal. The tincture of opium was given in order to prevent vomiting. But it will not always do so when the salol coat becomes broken, as is shown by the occurrence of vomiting in Case II.

It is necessary that each fecal discharge be carefully examined to find whether or not any of the capsules pass without being dissolved. In order to coat the capsules the salol should be heated in a small vessel until it is nearly all melted, the vessel should then be removed from the fire. A long pin should be stuck in one end of the capsule and dipped into the salol; by removing and rotating the capsule the salol may coat it uniformly; this should be repeated until a coat about three times the thickness of the wall of an ordinary capsule is obtained; the capsule is then removed from the pin and dipped in order to coat the point where the pin was inserted.

TRANSILLUMINATION IN LOCATING FOREIGN BODIES IN THE EXTREMITIES.

By MORRIS H. KAHN, M.D.,

NEW YORK.

INTERNE, MOUNT SINAI HOSPITAL.

Transillumination, as an aid in the diagnosis of diseases of the upper respiratory tract, has been extensively employed since its introduction by Voltolini, and its later development by Heryng. In minor surgery and in general medical diagnosis it has a quite untouched and widely applicable field. Especially is it of value in locating foreign bodies in the extremities.

The technique of transillumination of the extremities is simple. A small concealed electric lamp of ½ to 2 candlepower, such as the ordinary pocket lamp, is all that is necessary. A Coakley lamp is serviceable, and a monauricular stethoscope may be used as is done in the examination for hydrocele. The examining room should be totally dark and the eyes accustomed to the darkness before the examination is made. The lamp is then applied to the part to be examined, and the findings carefully interpreted. The light is transmitted through the soft tissues and also the fingers and toes. The web of the hands and feet is readily made translucent, and the palms may also be made translucent either by direct ventrodorsal or by lateral transmission. In adults a little light may be transmitted in the region of the wrist. In children the forearms and even the arms may be transilluminated to a degree depending on their adipose development.

In examining for a foreign body, the latter must be situated between the eye and the source of light, and it must be nearer to the eye than any obstacle in the field. Thus the shafts of the long bones are not translucent. When a foreign body is situated near the surface of a phalanx, that surface should face the examiner, or transillumination must be

made from side to side. Dark markings upon the skin, such as dirt on the fingers, ink stains, iodine or silver nitrate marks, and scabs or secretions become prominently apparent in these examinations. The superficial veins also become visible, but after compression they transmit the light. Folds of skin must be smoothed to admit of uniform translucency.

Because of obvious difficulties, the fluoroscope or the .r-rays are often not available in private practice. Even in hospitals and dispensaries the routine use of these for locating foreign bodies is expensive. Again, time elapses, and a needle fragment may be displaced within a few hours from its original position. Transillumination is, therefore, a ready aid. Splinters of wood are not revealed by the .r-ray, or they may break and large pieces may be left in the tissues unrecognized and form a pus focus. In these cases transillumination is valuable. In examining through an incision, tense connective tissue strands or fascia may impart through the examining probe "the feel" of a foreign body. With the foreign body visibly before one, however, no probing is necessary. The following cases are illustrative:

Case I.—Mrs. E. K., aged 24 years, had never received any injuries to her hands. One hour before she presented herself, while washing clothes, a needle, which had been left in the clothes, stuck into the palm of the right hand, and the point broke. The remaining portion was 2 cm. long. On examination, there was in the palm, just in front of the anterior transverse crease, one inch from the ulnar border, a black pinhead spot, slightly elevated, tender only on deep pressure, and surrounded by an areola one-quarter of an inch wide; no fragment was felt. Transillumination from the dorsum showed a dark line in the palm, 2 mm. long, shown also by illumination laterally from the ulnar border. The needle fragment then extracted was found lying slightly inclined in the antero-posterior axis of the palm. The length was 13 mm., and it was undoubtedly the perspective foreshortening that gave the measurement of 2 mm.

Case II.—Mrs. L. K., aged 40 years. Two hours before, while she was sewing at a machine, the needle pierced the right index finger through the nail toward the ball of the finger. The larger part of the needle was extracted from the back. Examination: Point of entry seen in middle of nail, and point of exit seen on outer aspect of the ball of the right index finger. Transillumination showed a linear shadow extending for 4 mm. backwards from anterior puncture. Under transilluminating light the needle was then extracted by making a small incision and grasping the point with an artery clamp. The fragment was 5 mm. long. In this case, transillumination served a purpose in addition to that of diagnosis. It was under guidance of transillumination that the needle was extracted. This method has two advantages over reflected lighting: First, the object sought for is always in view; secondly, blood is transilluminated and does not obscure the field. Even when no definite history is obtained, there is the possible presence of a foreign body. Moreover, the history is sometimes misleading, but transillumination is a simple means of verification. This is illustrated in the following case:

Case III.—Mrs. G. S., aged 33 years. No injuries to feet previously. About six hours before, while walking barefoot, the patient felt a sharp object stick into the ball of the right foot, and then extracted a needle fragment 2.5 cm. long, which had been submerged about one-quarter of an inch. Examination: Tenderness about the ball of the big toe, but no definite localization; no bleeding; no swelling. A small, dark point was seen where the needle was supposed to have entered. No foreign body was to be felt subcutaneously. Transillumination through the tissues of the ball and the outer portion of the foot showed the entire region clearly; no foreign body was seen. The diagnosis then made was that the eye end of the needle stuck into the foot, and the point broke against the floor. A radiographic examination subsequently made confirmed this diagnosis.

Case IV.—Miss E. M., aged 21 years. When she was six years old a piece of graphite was accidentally introduced into the right middle finger in front of the metacarpophalangeal crease. A subcutaneous nodule was to be felt. Dorsoventral illumination revealed this clearly.

Case V.—Miss J. L., aged 17 years. Twelve hours before, while she was sewing, the eye end of the needle stuck into the radial side of the nail groove of the right middle finger, and broke. The patient believed that a fragment was in the finger. Examination: Slight swelling, tenderness, and redness of inner side of first middle phalanx. Transillumination and subsequent fluoroscopy revealed no fragment.

Transillumination is also of value in general medical diagnosis. It is of use in certain cases of ascites, in hydrocephalus, prepatellar bursitis, in the early diagnosis of capillary venous thrombosis, in the discovery of the tender nodes in the fingertips in infective endocarditis, etc. Its application in detail is apparently unlimited, as will be shown in a future communication.

The Reaction of Agglutination and Precipitation in the Early Diagnosis of Pulmonary Tuberculosis.—Filippo Felici defines agglutination as a loss of mobility and grouping of masses of bacteria free and suspended in a culture medium. Agglutination occurs only with an acute infection and persists for a certain period. From the experiences of the author and other observers it appears that in tuberculosis the power of agglutination may be of importance, not appearing at all in healthy persons. If agglutination occurs in suspicious cases it has positive value as a diagnostic aid. Chronic cases should always be tested by this means. In apparently healthy persons, if it is found positive, it may indicate the presence of a tuberculous process that has lately healed.—*Gazzetta Medica di Roma.*

Physical Demonstration of the Thymus.—Basch and Rohn deal extensively with this subject, appending a bibliography. Their conclusions are as follows: Through the combination of accurate percussion in the mediastinal region, as carried out by a new instrument devised by the authors, and auscultation-percussion and auscultation for friction sounds, it was possible to ascertain the size and quality of the thymus in the child. The author investigated systematically 140 cases, learning thereby that the area of thymus dullness varies according to the age and state of nutrition of the child, and further with the presence of certain pathological conditions. Normally the area of thymus dullness has a rhomboid form. It extends from the throat above to the second or third rib below. Its lateral limits extend through the sternal and parasternal lines. These finds were checked up by autopsy cases.—*Deutsche medizinische Wochenschrift.*

THE NATURE OF NARCOSIS.

THE solution of the problem of narcosis is closely bound up with that of the problem of life itself. The veil behind which is shrouded the mystery of consciousness also hides from the penetrating eyes of science the mechanism that results in the abolition of this most important phenomenon of human life. To the philosopher and psychologist, but no more than to the physician, the problem is a fascinating one, and has led to a veritable maelstrom of speculation. By many investigators narcosis has been identified with inhibition, as to the nature of which a multitude of theories have been proposed. Inhibition has been regarded by Hering as a phase of anabolism; by Gaskell, as an expression of the checking of catabolism; by Lauder Brunton, as the result of interference phenomena in the vibrations in the nerve cells, analogous to similar phenomena in light and sound; by McDougall, as the result of a transference of nerve energy from one channel to another; by Schleich, as the consequence of a "short-circuiting" of the nerve current by the neuroglia; and by Wedensky, as a part and parcel of normal physiological life, usually latent, but frequently made manifest by numerous physical or chemical agents.

In an address before the Harvey Society, October 28, 1911, Max Verworn, the distinguished professor of physiology in the University of Bonn, pointed out that the subject of narcosis has been approached along two different lines of attack. The first of these culminated in a theory which has gained greatest acceptance among physiologists, namely, the theory elaborated independently by Hans Meyer and E. Overton, who found that the narcotic power of a substance depended upon its greater solubility in fats, as compared to its solubility in water, which would explain its ability to penetrate into the cell whose wall is rich in lipoids. But the Overton-Meyer theory, while it may explain how the narcotics gain entrance into the intricate recesses of the cells, fails to throw light upon the most obscure of all physiological phenomena, the inhibition of vital activity.

The explanation must be sought in the second line of attack. Cláude Bernard attributed narcosis to the coagulation or semicoagulation of the protoplasm. This was later demonstrated by Binz in unicellular organisms subjected to the influence of narcotic drugs. The speaker pointed out that narcosis is characterized by a stage of depression or retardation of vital activity. This retardation may be the result of heat or of cold, of fatigue, suffocation, intoxication, an osmotic pressure that is too low, and restriction of food. Not all the forms of depression are the same, but there is a tendency toward one type, namely, the depression caused by the poverty in oxygen. Fatigue is a manifestation of relative oxygen-starvation, while in heat depression the supply of oxygen can not keep pace with its consumption. In hydrocyanic acid poisoning it is the suppression of oxygen that produces death in the aerobic organism.

If narcosis is related to the internal respiration of the tissues, then the investigation of the methods in which the latter is accomplished would aid in throwing light upon the former. Attention is centered in the oxidases, or oxygen carriers, which activate the oxygen, drawing it from the complex molecules in which it is stored, and making it available for instant use. Oxidative catabolism of the cells proceeds, in the shutting off of the external oxygen supply, until the stored up oxygen is exhausted, and is succeeded by nonoxidative catabolism. Verworn advances the hypothesis that narcosis is similar to an interference with the oxidative processes. He has been able to show experimentally that fatigue in the spinal cord of the frog may be removed by irrigating the cord with arterial blood of the ox, in this way providing a fresh supply of oxygen. During the process of narcosis the cells are not able to utilize the oxygen that may be within their reach. Destructive metabolism may still go on in the nonoxidative form just as it does in the case of asphyxia. The entire symptom-complex of narcosis is identical with that of asphyxia. There is only one point of difference, and that is the time relation. In narcosis the irritability of the cell is suppressed in a few minutes, while in asphyxia this suppression may take as many hours. In asphyxia the power to carry on oxidation is not diminished; the irritability diminishes gradually, depending upon the amount of oxygen stored up in the cell. Narcosis is a form of acute asphyxia, caused by depriving the cell of the power of carrying on oxidation.

The question now arises: In what way does the narcotic act? The explanation must be sought in some stage of the utilization of molecular oxygen. There are four alternatives in this working hypothesis. First, it may be advanced that the narcotic prevents the entrance of molecular oxygen into the cell. This hypothesis can be readily dismissed; for, if the cellular depression were due to the nonpenetration of oxygen, then one would expect the same time relations as in ordinary asphyxia, which is not the case. Second, it may be suggested that the narcotic appropriates the oxygen for its own use. Although it has been shown that narcotics may be oxidized, it is doubtful whether this occurs to any considerable extent. Third, the hypothesis has been advanced, but without proof, that the narcotic blocks the molecules of the cell, preventing the oxygen from reaching them. Fourth, the narcotic may render the oxidases unable to do their work.

This is the most plausible hypothesis, and appears to be supported by the weight of experimental evidence.

As part of this evidence it has been shown that the colloidal metals which act as oxidases lose this property when subjected to the influence of various substances, such as hydrogen sulphide, corrosive sublimate, and hydrochloric acid. The solubility of the narcotics in the cellular lipoids may in some manner deprive the oxidases of their oxygen-carrying powers. This hypothesis would harmonize with the Overton-Meyer theory. Another important point to be considered is the fact that the ganglion cells of the cerebral cortex are the first to succumb to narcosis and are at the same time most sensitive to asphyxia. Thus Mosso, by means of compression of the carotid artery, was able to produce unconsciousness in a few minutes.

The phenomenon of narcosis has been identified with sleep. But the analogy is only a superficial one. Both phenomena are attended by a loss of consciousness, but not every loss of consciousness is sleep. In narcosis the process of oxidation is inhibited, while in sleep this process continues. In fact, the purpose of sleep is to enable the cells to recover from the state of fatigue by the utilization of oxygen—in other words, sleep is a phase of restitution. Verworn's conception of the nature of narcosis is a most ingenious one, furnishing evidence of that clear insight into fundamental cellular processes for which the author of "General Physiology" is so well known. The practical deduction from this hypothesis is obvious: it indicates that narcosis is associated with an interruption in the normal activity of the cells, with a suspension in the process of oxidation upon which the manifestation of life depends. Narcosis verges close on to death.

CARDIOMYOPATHIES.

Myopathies of the heart may be divided into athletic heart so called, constitutionally weak heart, myodegeneration, and fatty heart of the obese, while in the same connection should be considered reflex cardiac disturbances and cardiac neuroses. Myodegeneration is an extensive subdivision which is concerned with both infections and intoxications (tobacco heart, etc.), as well as traumatism. Constitutionally weak heart is a theoretical affection which is in evidence, if at all, in rapidly growing youths.

In the *Berliner klinische Wochenschrift* for October 9 Dr. Hirsch, a woman physician connected with Charité Hospital, Berlin, gives a digest of the literature of cardiomyopathies which has appeared during the past four years. Writers on athletic heart are very largely American or British, although on the continent of Europe considerable research has been made into the heart of the bicycle rider, wrestler, and swimmer. In some sports the prolonged training for an event, rather than the contest itself, is at fault. Predisposition must play an important rôle, as is shown in the case of the girl who died suddenly with a heart hypertrophied from playing basketball. The so-called "cadet heart," which is believed to result from the custom of drilling and marching in closely fitting, heavy, and inelastic uniforms, is not here mentioned by Dr. Hirsch. The belief in an acute dilatation of the heart as a result of overexertion seems to have been dispelled by orthodiagraphic researches. An athletic heart represents a simple hypertrophy from overwork. Weston's recent feats appear to point to the fact that walking in the open air entails none of the perils of athletic heart. That one athlete is active and robust at an advanced age while another is short lived appears to be due both to individual predisposition and to the character of the exercise. A man "made of poor goods" may train himself gradually to feats of strength and endurance, and his early demise cannot altogether be set down to athletic heart.

Under the general management of myodegeneration it is to be noted that morphine is regarded by some authorities as the best heart tonic. Heroine also has advocates. Both these drugs relieve cardiac dyspnea. Rest is much less indicated in a primary myopathy than in myopathy secondary to valvular disease. The discovery made some years ago that an acute dilatation of the heart is very commonly present in acute infectious diseases has been amply verified. Twenty years' study of the pandemic of influenza has shown the influence of the latter in the causation and aggravation of cardiopathies. It must not be assumed that these diseases necessarily set up a myocarditis. True inflammation of the myocardium is due perhaps more frequently to syphilis than to any other infectious diseases. The disease toxins do set up acute dilatation, and while this is usually self-limited, exceptions are not uncommon. The so-called rheumatic nodules which form in the myocardium and prejudice the normal heart action may perhaps occur after other infectious diseases, although this is in dispute. Of myodegeneration from intoxications the principal endogenous type is the thyreotoxic. Of exogenous types those due to alcohol, tobacco, and chloroform (narcosis) are best known. Functional affections of the heart comprise those due to upward pressure of an unnaturally high placed diaphragm, of a stomach distended by gas, etc. The symptoms do not differ materially from those of cardiac neuroses. The heart of the corpulent subject should not be regarded as a necessarily diseased organ.

BABINSKI'S PHENOMENON IN PREUREMIA.

Uremia and preuremia are not usually reckoned among nervous affections despite the presence of well marked symptoms of cortical origin. This is not surprising, because epileptiform convulsions and other evidences of disturbance in the higher nerve centers occur as incidental or terminal phenomena under the most varied circumstances. This is especially the case in severe types of intoxication of any sort, in which the nervous system is involved with other organs of vital importance, some poisons being naturally more neurotropic than others. As our knowledge of uremia increases, however, it presents more and more evidence of a neuropathic character. These cases are usually treated by the general practitioner, who seldom summons a neurologist

in consultation. An expert neurological examination, however, made at a period when uremia is only a possibility, would doubtless often reveal impending symptoms of this condition. The mental faculties are tested as to the degree of attention, perception, memory, etc., and the mental state as to cheerfulness and the reverse. As the sensorium becomes clouded in uremia, these tests in possible preuremia often shed light on what may follow. The field of vision, acuteness of vision, and color and form perception are also investigated. All the well known diagnostic tests of reflexes may be applied, with especial reference to the Jacobssohn finger flexor reflex, the tendon and periosteum reflexes, the cremaster reflex, the phenomena of Kernig and of Babinski, etc.

In the *Münchener medizinische Wochenschrift* of September 26 Curschmann attributes the greatest importance to a positive Babinski phenomenon in preuremia. Considerably before the likelihood of uremia is heralded by increased reflexes, clouded sensorium, etc., he has found a preliminary depression of reflexes, which he discovers to be more constant and characteristic than the increased reflex excitability which may follow it, and along with the extinction of the patellar reflex and other tendon reflexes he finds associated the Babinski phenomenon. Moreover the latter may occur quite alone in preuremia. While the author nowhere uses the word pathognomonic in this connection he clearly believes that the phenomenon possesses the greatest diagnostic value.

Investigation of Sprue.

The suggestion is said to have been made recently by some British observers that there was sufficient resemblance between sprue and pellagra to warrant the surmise that they might be one and the same disease. It is very unlikely that there will be found to be more than a superficial resemblance between the two affections. Nevertheless the report from Great Britain that a thorough investigation of sprue is to be undertaken arouses the hope that our knowledge of this disease will be enlarged. Sprue, or psilosis, is a troublesome and serious affection which may last for years, producing great emaciation and weakness from the persistent diarrhea which is nearly always an accompanying feature. Manson describes it as an "insidious, chronic, remitting inflammation of the whole or part of the mucous membrane of the alimentary canal. It occurs principally in adult Europeans who have resided in warm climates, and is chiefly met with in Ceylon, the Straits Settlements, Java, parts of China, Manila, and occasionally elsewhere. Its origin is unknown, although believed to be bacterial. The Ceylon government has offered the London School of Tropical Medicine a sum of $3,750 to investigate, and it is expected that a further sum of $1,250 will be provided by the Ceylon Tea Planters' Association. Definite arrangements have not yet been made as to who will conduct this investigation, but the mere fact that the investigation is to be undertaken by a member of the London School of Tropical Medicine is in itself an earnest that faithful work will be done. Perhaps the etiology of yet another of the diseases which render tropical climates so harmful to the health of the white man will be discovered and a means of treatment or prevention evolved which will nullify its potentialities for evil.

Constitutional Remedies in Affections of the Eye.

The benefits derived, even in certain nonsyphilitic diseases of the eye, from mercurials and iodides, and the favorable action of tuberculin in ocular tuberculosis suggests the possibility that other substances of general local action may also possess some curative power when given subcutaneously or by the mouth. Antistaphylococcic and antipneumococcic sera have been tried with favorable result in cases of sepsis in the eye tunics and chambers after a bacterial diagnosis has been made. Thiosinamine and stypticin have been tested in injuries of the eye from foreign bodies, with the view of facilitating healing and preventing hemorrhage. The former has been injected into the buttocks, while stypticin has been given by the mouth. The efficacy or non-efficacy of these remedies thus given cannot, however, readily be determined. At a meeting of the Aerztlicher Verein of Frankfurt (*Münchener medizinische Wochenschrift*, September 26) Emanuel considers the entire subject of the effects of constitutional remedies in ocular diseases. The most striking feature of his article is the great field for mercurials in these affections. These are used freely in traumatic affections, including foreign bodies, in sympathetic ophthalmia, as adjuvants to tuberculin, and generally speaking, in all affections in which there is any suspicion of lues. Perhaps in any obscure chronic or subacute affection of the eyes, even in the absence of positive biological tests for syphilis and tubercle, it is wise to submit the patient to a mercurial and tuberculin treatment, for the mechanism of the action of these substances is by no means fully understood and the latter may transcend a merely antidotal function.

News of the Week.

Food Inspection in New York City.—The Department of Health, as a result of inspections and arrests made through the Division of Food Inspection, has brought proceedings against twenty-seven individuals for violation of various sections of the Sanitary Code. It is apt to be thought that all proceedings begun, and convictions obtained, for violations in connection with the sale of food and drugs are the result of prosecutions by the Federal authorities under the Federal Pure Food and Drug Law. While this misapprehension is, perhaps, not unnatural, it sometimes results in failure to appreciate the fact that the local health authorities have full jurisdiction over the matter of foodstuffs offered for sale in the city of New York. Numerous provisions of the Sanitary Code of the Board of Health forbid the sale of food which is adulterated, or in any way unfit for human consumption. These cases, like those which are regularly brought in this court every two weeks at the instigation of the Department of Health, charge violations of these provisions in a large variety of cases where eggs, candy, ice cream, milk, pies, meat, vegetables, frankfurters, and fish have been condemned by the inspectors of the Department.

Conference of Municipal Health Officers.—The eighth annual conference of health officers in the State of New York was held in this city on

Wednesday, Thursday, and Friday of last week. Dr. Eugene Porter, State Commissioner of Health, presided, and the address of welcome was made by Dr. Ernest G. Lederle, Health Commissioner of New York City. The subjects discussed in the first day's session were The Registration of Communicable Diseases, Quarantine in Cities and Rural Communities, Disinfection, and the Control of Syphilis and Gonorrhea. In discussing quarantine Dr. H. S. Swain of Corning scored those physicians, who were still in existence, who would visit a person with contagious disease and go immediately to other patients without taking any precautions in the way of disinfection of self or clothing. Dr. William D. Perkham argued against hard and fast rules governing the manner and length of quarantine in case of a person with contagious disease. Dr. Frederick B. Willard of Buffalo regarded street cars as perhaps the most effective means of the dissemination of contagious disease. They were seldom properly cleaned, he said, and were practically never disinfected. On the program for the discussion of the control of venereal diseases were Drs. Prince A. Morrow, Abram Jakobi, and Edward L. Keyes. On Thursday there was a conference on "Interstate Health Problems," which included the subjects of stream pollution, pure food, and cold storage. In the matter of stream pollution, the enactment of a national law against this practice was urged, and this suggestion was supplemented by Dr. Laurence McCullough of the Ontario Health Department, who advocated the creation of an International Waterway Commission, to prevent the present careless dumping of sewage into the rivers and lakes between this country and Canada. As to cold storage, the recommendation was made that a dated label should be attached to every package of cold storage food. Speaking on the topic of "A Clearing House of Health Departments," Mr. Robert Lynn Cox, counsel for the Association of Life Insurance Presidents, declared that a majority of Health Departments throughout the country were not properly equipped. Hundreds, he said, to whom he had written for copies of their reports, had replied that they were not allowed sufficient money to print reports. In order that the Health Departments might get together for the discussion of general health measures throughout the country, he urged the establishment of such a clearing house. Dr. William H. Guilfoy, Registrar of the New York City Department of Health, read a paper on "Vital Statistics and How to Get Them," and Dr. Charles E. Walton of Cincinnati spoke on the topic of "The Doctor and the Health Officer as Colaborers." On Friday Dr. Simon Flexner spoke on "Research in Public and Private Laboratories," taking as his text the work of the Rockefeller Laboratory and his discovery of a curative serum for epidemic cerebrospinal meningitis. Dr. W. S. Magill, director of the State Hygienic Laboratory, made a plea for the more general and the earlier use of antitoxin in diphtheria. In France, he said, where diphtheria antitoxin was very widely used, the diphtheria mortality was 3 in 100,000, whereas in this country it was 16 in 100,000. On Wednesday afternoon the delegates visited the Budget Exhibit of the New York City Department of Health. On Thursday afternoon the program provided for an inspection of the Quarantine Station on Staten Island, and on Friday afternoon the visiting health officers were conducted through the Rockefeller Institute.

The Alvarenga Prize.—The College of Physicians of Philadelphia announces that the next award of the Alvarenga Prize will be made on July 14, 1912, provided that an essay deemed by the committee of award to be worthy of the prize shall have been offered. Essays intended for competition may be upon any subject in medicine, but cannot have been published. They must be typewritten, and if written in a language other than English should be accompanied by an English translation, and must be received by the secretary of the college on or before May 1, 1912. The prize for 1911 has been awarded to Dr. Francis D. Patterson of Philadelphia, Pa., for his essay entitled, "The Parathyroid Glandules."

Civil Service Examination.—A number of civil service examinations for medical positions have been held in this city during the past week. One of the positions was that of medical inspector of the Board of Health; the salary attached is $1,200, and there was 396 applications. The next most sought for appointments are those of surgeon to the Police and Fire Departments; the salary of the first is $3,500, that of the second $3,300; one examination applies to the two appointments, and the applicants numbered 315. The coroner's physicians have a salary of $3,000 in three of the boroughs and $1,500 in two; there were 118 applicants. The examination for positions of general medical superintendent and medical superintendent of public hospitals, the former having a salary of $5,000, the latter of $3,000 to $4,000, attracted but 25 applicants; and that for deputy medical superintendent of hospitals and farm colony, with a salary of $1,000, was attended by 9 candidates. Candidates for these public hospital positions were not required to be residents of the State of New York, but it was demanded that they be licensed to practise in the State. A curious condition, and one that would bar most applicants, was that the candidates must have been in practice ten years and during that period must have had five years' hospital experience. The conditions for deputy superintendent were five years of practice including three years' hospital experience.

Hospital Distribution.—At the October meeting of the Medical Society of the County of New York a protest was presented on behalf of the Polyclinic Hospital against the removal of the New York Hospital to the river front in close proximity to the former. The Polyclinic Hospital, it was urged, had decided to build on West Fiftieth street because Roosevelt Hospital had given up its ambulance service, leaving the neighborhood poorly provided for. The contention was that the medical and surgical service of that vicinity should be left to the firstcomer and that the New York Hospital should go to the Bronx, where such an institution was badly needed. On the other hand it was asserted that that part of the city is rapidly growing and that its needs would not be met by the 300 beds of the Polyclinic Hospital. A resolution was introduced embodying the protest of the Polyclinic, but was referred to the Committee on Hospitals and Budget.

A Memorial Hospital in Lakewood.—It is announced that a hospital will soon be built in Lakewood, N. J., in memory of Dr. Paul T. Kimball, for nearly forty years a practitioner in that town, who died about a year ago.

Special Study of Pellagra.—The Department of Tropical Medicine of the New York Post-

Graduate Medical School is organizing an expedition to investigate pellagra in the Southern States. The work will start in the spring and is made possible by the gift to the institution for this purpose of $150,000 by Col. Robert M. Thompson and Mr. J. H. McFadden.

The Chicago Surgical Society.—At the annual meeting of this society on October 20 the following officers were elected: *President,* Dr. Frederick A. Beasley; *Vice-President,* Dr. Samuel C. Plummer; *Secretary,* Dr. Allan B. Kanavel; *Treasurer,* Dr. Dean Lewis.

Mississippi Valley Medical Association.—At the annual meeting of this society, held in Nashville, Tenn., October 17-19, the following officers were elected: *President,* Dr. Louis Frank of Louisville; *First Vice-President,* Dr. Albert E. Sterne of Indianapolis; *Second Vice-President,* Dr. F. W. Werner of Joliet, Ill.; *Secretary,* Dr. Henry Enos Tuley of Louisville; *Treasurer,* Dr. Samuel C. Stanton of Chicago. The meeting in 1912 will be held in Chicago.

The Seaboard Airline Railway Surgeons met in annual session in Washington, D. C., on October 17 and 18. The following officers were elected: *President,* Dr. S. C. Benedict of Athens, Ga.; *First Vice-President,* Dr. H. J. Buckey of Portsmouth, Va.; *Second Vice-President,* Dr. R. L. Harris of Jacksonville, Fla.; *Third Vice-President,* Dr. J. H. Miller of Cross Hills, S. C.; *Secretary and Treasurer,* Dr. J. M. Palmer, of Ailey, Ga. The next meeting will be held in Tampa, Fla.

Brookfield, Mass., Medical Club.—At the annual meeting of this society, held October 18, the following officers were elected: *President,* Dr. E. W. Norwood, Spencer; *Vice-President,* Dr. Homer V. Leach, Gilbertville; *Secretary-Treasurer,* Dr. Hyde L. Edmunds, North Brookfield; *Executive Committee,* Drs. E. A. Ludden, Mary Sherman, and L. T. Newhall.

Anson County, N. C., Medical Society.—This society was organized at a meeting held October 16, at Wadsboro, N. C. The following officers were elected: *President,* Dr. J. H. Bennett; *Vice-Presidents,* Drs. Ashe and Ross; *Secretary-Treasurer,* Dr. J. E. Hart.

Wyoming County, N. Y., Medical Society.—At the annual meeting of this society, held at Warsaw October 9, the following officers were elected: *President,* Dr. Martin of Cowlesville; *Vice-President,* Dr. Peddle of Perry; *Secretary and Treasurer,* Dr. Humphrey of Silver Springs.

Vermont State Medical Association.—At the 98th annual meeting of this society, held in Burlington the second week in October, the following officers were elected: *President,* Dr. F. T. Kidder, Woodstock; *Vice-President,* William Lindsay, Montpelier; *Secretary,* C. H. Beecher, Burlington; *Treasurer,* C. F. Dalton, Burlington; *Auditor,* A. M. Norton, Bristol. The next annual meeting will be held in Montpelier in October, 1912.

Cornell University Medical College opened on Wednesday, September 27, with an enrolment as follows: First year, 32; second year, 23; third year, 20; fourth year, 11; special students (work not leading to the degree), 19; doctors of medicine engaged in research, 9; total, 114. There is a loss in numbers as compared with the preceding year which is due to the fact that all matriculants for the degree of M.D. now registered are admitted under the advanced requirements necessitating the prsentation of a bachelor's degree in science or arts, together with something more than one year's work in physics, chemistry, and biology.

The Medical School of Maine, the medical department of Bowdoin College, opened Thursday, October 19, for registration of students. This year marks the 92nd course of lectures given by this school. Two members of the faculty, Dean Alfred Mitchell and Dr. Frederick H. Gerrish, have resigned. The registration is expected to show considerable increase over that of last year, which was 67.

Report from Canal Zone.—During the month of August the deaths from all causes among employees numbered 38, of which 26 were due to disease and 12 to violence, giving an annual average per thousand of 6.27 and 2.90 respectively. The annual average death rate among employees for the month of August of each year is as follows:

1904	13.93
1905	19.97
1906	62.12
1907	27.59
1908	11.39
1909	10.28
1910	13.04
1911	9.17

Among the population of Panama, Colon, and the Canal Zone the rate during August in the previous years is given as follows:

1905	51.05
1906	64.12
1907	33.75
1908	26.65
1909	16.20
1910	19.85
1911	20.31

Among employees the deaths from the principal diseases were: Chronic nephritis, 3; hemoglobinuric fever, 4; lobar pneumonia, 4; malarial fever, 1; tuberculosis, 4; typhoid fever, 1. During the month 19 cases of diphtheria were reported, 14 from the Canal Zone, 3 from Panama, and 2 from Colon, with 1 death. The type of the disease was mild. No cases of yellow fever, smallpox, or plague originated on or were brought to the Isthmus during the month.

Southwestern Medical Association.—At the sixth annual meeting held in Oklahoma City, Okla., on October 9 and 10, the following officers were elected: *President,* Dr. A. L. Blesh of Oklahoma City; *Secretary,* Dr. F. H. Clark of El Reno.

Westbrook (Me.) Medical Club.—The following officers were elected at the annual meeting held on October 10: *President,* Dr. Charles Haynes of Gorham; *Vice-President,* Dr. Felix Barrett of Westbrook; *Secretary-Treasurer,* Dr. F. L. Ferren.

Lane County (Ore.) Medical Society.—The following officers have been elected for the ensuing year: *President,* Dr. Charles W. Southworth; *Secretary-Treasurer,* Dr. G. L. Beardsley.

Fairfield County (Conn.) Medical Association.—At the 119th semi-annual meeting on October 3 the election of officers resulted as follows: *President,* Dr. William L. Griswold of Greenwich; *Vice-President,* Dr. James P. Gold of Bridgeport; *Secretary,* Dr. Frank W. Stevens of Bridgeport; *Treasurer,* Dr. Philip W. Bill of Bridgeport.

New Bedford (Mass.) Medical Society.—The election of officers at the annual meeting on October 9 resulted as follows: *President,* Dr. Charles Bonney; *Vice-Presidents,* Dr. C. J. Leary and Dr. Edmund F. Cody; *Recording Secretary,* Dr. David D.

Pratt; *Corresponding Secretary,* Dr. Eric St. John Johnson; *Treasurer,* Dr. E. E. Foster.

Second District (Ia.) Medical Society.—The election held at Davenport on October 10 resulted as follows: *President,* Dr. E. H. King of Muscatine; *Vice-Presidents,* Dr. E. B. Henderson of Marengo and Dr. H. G. Reynolds of Clinton; *Secretary-Treasurer,* Dr. John V. Littig of Davenport.

Southern Medical Association.—The annual meeting of the association will be held in Hattiesburg, Miss., on November 14 to 16, 1911.

Obituary Notes.—Dr. Helene Knabe of Indianapolis was found murdered in her apartment on October 24. She was born thirty-five years ago in Germany and came to this country early in life, working her way until she was graduated from the Indiana Medical College in 1904. Before graduation she was appointed instructor in bacteriology at the college, and later was appointed assistant pathologist in the Hygienic Laboratory of the Indiana State Board of Health. She was professor of parasitology and hematology in the Indiana Veterinary College. She was a member of the Indianapolis Medical Society, the Indiana State Medical Society, and the American Medical Association.

Dr. Forrest B. Seymour of Beeville, Texas, a graduate of the Medical College of Ohio, the Medical Department of the University of Cincinnati, in 1889, died at his home on October 7 after a long illness, aged 45 years.

Dr. William H. H. Hagey of Norfolk, Neb., a graduate of the Rush Medical College, Chicago, in 1868, and a member of the Nebraska State and Madison County Medical Societies, died at his home on October 8 of apoplexy, aged 70 years.

Dr. George W. Hogeboom of Topeka, Kan., a graduate of the Boston University School of Medicine, Boston, in 1852, a member of the Kansas State and Shawnee County Medical Societies, died at his home on October 8, aged 79 years.

Dr. George Frederick Jelly, for thirty years State Examiner of the Insane for Massachusetts, died October 24 at his home in Wakefield, aged 68. Dr. Jelly had been in failing health for several months and indications of a nervous breakdown had caused him to resign his office in July. He was graduated from Brown University in 1864, and in medicine from the Harvard Medical School in 1867. He at once began practice in Springfield, making a specialty of nervous and mental diseases. In 1869 he was called to the Waverly asylum as assistant physician and in 1871 became superintendent, relinquishing the position in 1879 to take up private practice in Boston. When the State Board of Insanity was organized in 1898, Dr. Jelly was made its first chairman.

Dr. Samuel A. Helfer of Hoboken died October 24 at his home in that city, in his 68th year. He was born at Budapest, Austria, and was educated at the University of Vienna. He came to America in 1874 and opened an office in Hoboken. He held the office of city physician and acted as physician for steamship companies for many years. Dr. Helfer was decorated by the French Government with the cross of the Legion of Honor and by the Emperor of Austria with the Order of Merit.

Dr. John A. Warner, a graduate of the Albany Medical College of the class of 1847, died in Saratoga October 23. He was 88 years old. Dr. Warner practised medicine in New York for fifty years and retired several years ago.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent)

SOCIETIES OPEN—INSURANCE BILL, CONFERENCE WITH LLOYD GEORGE, FRIENDLY SOCIETIES' MEETING, ETC.—SIR T. OLIVER ON PLUMBISM—ITEMS—OBITUARY.

London, October 13, 1911.

The societies are settling down to the work of the new session. On Monday the Medical Society of London had an interesting presidential address from Dr. Mitchell Bruce, after which Dr. Leonard Guthrie read a paper on recurrent jaundice with pyrexia occurring in a girl 11 years of age in which there was marked anemia with splenomegaly and pigmentation of the skin. In his address the president pointed out that the society and medicine in general would profit if a larger number of general practitioners would take part in the proceedings. As often before has been remarked, some aspects of disease can only be studied by general practitioners since they only have the opportunity of seeing them in all their stages.

On Wednesday at the Hunterian Society Dr. T. B. Hyslop delivered the first of his Hunterian lectures, taking for subject, intracranial murmurs and their relation to tinnitus aurium.

The same evening at the United Services Medical Society the presidential address was delivered by Major E. M. Pilcher, D.S.O. He devoted it to the new bullet, a subject no doubt specially interesting to army officers.

The West London Medico-Chi. opened on the 6th inst. when the new president, Mr. McAdam Eccles gave an address on the "Future of Surgery." Remarking that surgery had had a great past he asked what is to be its future? To estimate its progress he referred to the advances made in the last 25 years at St. Bartholomew's Hospital, to which he is one of the surgeons. He then asked further whither is it all tending, and answered that medicine has let the surgeon enter where she alone previously stood, the result being that both in hospital and private practice the surgeon has more cases first hand than formerly. All that surgery can achieve was rendered possible by Lister, who proved that the removal of, and the exclusion from a wound, of organisms is the one essential for success, and the first lesson for nurse or dresser to thoroughly master. Passing on to the factors contributing to the advance, he mentioned: (1) Improved methods of diagnosis, particularly by new instruments, which enable us to see areas of the body previously invisible. (2) Investigation by *x*-rays, especially in fractures. The old plan of leaving a closed fracture alone, for if the true position of the bones can be seen by the rays the surgeon can cut down and unite the fragments. (3) The better training and higher skill of surgical nurses. Mr. Eccles declared himself a strong advocate of thorough training. Many nursing homes had been unfit for surgical work. They must be fully and properly equipped and need not be too costly or elaborate. The problem as to middle class patients might be profitably discussed by their society, said the president. In the country he looked for improvements, as the local surgeons would be better equipped for emergencies. There was a danger, continued the speaker, of neglecting the non-operative side of their art, and the day was near when the teaching of our out-

patient departments must be remodeled. The number of accidents has greatly increased and will increase still more and will greatly change the work of the general practitioner. The clauses of the National Insurance Bill were sadly defective of provisions for operative surgery. In conclusion the president urged the importance of recording the after process of cases from the point of view of the practitioner in charge as sure to be of considerable value.

The promised conference between Mr. Lloyd George, the Friendly Societies and the Medical Association opened at the Treasury on Monday. The subject was assumed to be to consider the objections raised by the societies to certain provisions of the Insurance bill and some points raised by the B. M. A. For the societies their views as to the health committees, which I have in former letters stated, were represented and somewhat enlarged. Their spokesman held that arrangements ought to be made for chronic invalids, and those over 65 should continue to receive such medical benefits as they now enjoy—that insured persons should have the personal care of the doctor chosen and no substitute or assistant. Farther when certain new societies were formed the other local doctors should not be allowed to ostracise those who attended them. You will see by these demands what very strange opinions are held about the profession by some officials of the clubs. Dr. Whittaker commented on the points put forward, and a general discussion followed which, I am told, tended to narrow down the differences and that probably the doctors and societies will come to a settlement. The conference adjourned until next Monday, when the representations of the B. M. A. will be taken up.

Another conference was also held on Monday—on one of the smaller societies. They demand that the limit of the number of approved societies shall not be more than 5,000 instead of 10,000 of the bill. A reputation was appointed to wait on the Chancellor of the Exchequer on this question.

Yesterday the annual conference of Friendly Societies was opened and the bill fully discussed. The minimum demands which those societies were willing to accept were formulated and agreed to. They comprise, so far as the medical ones are involved, those which I have previously reported to you. There seems a distinct division among members as to the bill. One party is for killing it outright; the other for accepting if the government will embody their amendments. It was asked at the meeting what would be done if the demands were not conceded. The supporters of conditional acceptance declined at first to commit themselves, but as the meeting insisted on an understanding, it was eventually said that on the government refusing those terms, the committee would recommend all societies throughout the country to strenuously oppose the bill. An amendment was proposed, on account of the far-reaching nature of the scheme and its complexity, that more time was needed for the country to consider it, and that therefore it should be held over for next year—especially as so far the Chancellor had granted only six out of fifty requests made by the societies. The amendment was lost. During the week there has been a rumor that Mr. Lloyd George was determined to pass his bill this year and to do so, would on parliament meeting put in force the closure by paragraphs. He might as well declare himself an autocrat and dismiss parliament as a useless machine.

Among the subjects set down for discussion at the late Church Congress was "Industrial Employments and Their Dangers." Sir T. Oliver attended the meeting to testify as a medical man to the value of recent regulations issued by the Home office as to pottery. He urged that manufacturers ought to utilize every resource of science and asked if it was too much to expect them to keep an open mind as to the possibilities of leadless glaze. Workpeople should be encouraged to tell the doctor without delay of any derangement in their health, as it was so much easier to deal with lead poisoning in the early than the late stages. Sir Ernest Hatch afterwards said the public would do much by insisting on leadless earthenware when purchasing. He added that the inhalation of dust in pottery works was at times more injurious than exposure in the glazing departments. Progress towards stricter supervision might be more rapid and the staff of factory inspectors should be largely increased.

The King has formally approved the election of Sir T. B. Crosby as Lord Mayor for the coming year, and he will take up the duty on November 9. The outgoing Lord Mayor, Sir T. Vezey Strong, has issued as usual an appeal on behalf of the Hospital Saturday Fund. The income for 1910 exceeded that of the previous year by over £4,000, and his Lordship hopes for a still better collection this week.

Dr. George Saunders, C.B., is president of the London Medical Mission and has this week kept his 88th birthday. He works at the Mission and enjoys excellent health, although he has had a most eventful career. He entered the army medical service as a young man, went to the Crimea, where he endured the hardships of that terrible war, was in most of the battles, and after that was in China, Japan, South Africa, and indeed seems always to have been where there was hardship, and always trying to set the authorities to alleviate it—often in vain. Once he secured his object by becoming personally responsible for the cost up to £2,000. He is a Dr. Inspector-General—a civilian might think that not enough for such a life devoted to his country, and surely his C.B. might have gone a step or so further.

The Anti-Vaccine League is nursing a grievance against the Asylums Board for refusing access to the registers on the ground that the league is not a sanitary authority. The act authorizes only such authority to examine and copy the registers. The league appealed to the local government board, but its hospitals committee did not see their way to interfere. A motion was made at the Asylums Board to permit the league to examine the register in the manager's office, and a member thought it would be courteous to do so and undignified not. But his proposal was rejected by a large majority.

Another of our veterans has passed away. Dr. Hughling Jackson died on the 7th inst., aged 76, and his loss will be felt wherever clinical medicine is studied. It has been said that his work produced order in neurology where confusion previously reigned. He was apprenticed a practitioner in York as customary in those days, and qualified at College and Hall in 1856. He filled his curriculum at the York school, but also attended for a session at St. Bartholomew's Hospital, where Sir Joseph Paget was teaching. In 1860 he took the M. D. St. Andrews and the M. R. C. P. Lond.

and entered on practice. Two years later he was on the staff of the hospital for epilepsy and paralysis, where he worked until 1902 when he became consulting physician. A little later he was on the staff of the London Hospital, to which also he became consulting physician. In 1868 the College of Physicians elected him a fellow and Gulstonian lecturer. By this time his work on aphasia and other nervous diseases was widely known, and although his conclusions were not generally accepted the conviction that they were correct was widespread and extending. In fact his reputation as an exact clinical observer and accurate reasoner has been growing ever since. In the Croonian lectures in 1884 he stated his views on the evolution and dissolution of the nervous system, which he had been brought to after long observation. In the Lumleian lectures in 1890 he detailed the conclusions to which he had been brought. In the meantime he had served the college as councillor and censor. He was elected F.R.S. in 1878, and honors were showered upon him by various societies, academies and universities in various countries. British politicians did not know how to honor one of the most scientific investigators of medical problems. The Neurological Society, founded in 1885, elected him first president and established a lectureship called by his name, which has been devoted to the illustration of his work and the commemoration of its ever extending results. His writings are too numerous to mention—you know the most important. While all the medical world is thinking of his researches and their effects, it seems to me that those who knew him are most admiring the patient observation with which he pursued his clinical studies and research.

Dr. William Richard Huggard died on the 9th inst. He has been British Consul at Davos for the last 25 years. He was a graduate in Arts and Medicine of the Royal University, Ireland, 1875-9, F.R.C.P. Lond. 1898. He wrote a "Handbook of Climatic Treatment," and contributed to the medical societies and journals on insanity, on phthisis, etc. At the tuberculosis congress in 1902 he had a paper on the use of drugs in pulmonary tuberculosis.

Brigade-Surgeon Alexander Dugald Campbell, late of H. M. Bengal Medical Service, died on the 8th inst., aged 77.

Dr. John Highet, medical health officer for Workington for the past 20 years, died on Monday night after a long illness, at the age of 60. He was a Glasgow graduate and wrote a work on "State Obligations in Matters of Public Health." He was a magistrate for his county (Cumberland).

OUR LETTER FROM COPENHAGEN.

(From Our Regular Correspondent.)

TREATMENT OF LUPUS OF THE NASAL MUCOUS MEMBRANE BY THE PFANNENSTILL METHOD.

COPENHAGEN, September 28, 1911

At the first congress of Scandinavian oto-laryngologists held in Copenhagen a short time ago, Dr. Ove Strandberg read an important and interesting paper on the Pfannenstill treatment of lupus of the nasal mucous membrane, the technique of which he had worked out on the rich material of the Finsen light-institute of Copenhagen. As mentioned in a former letter of mine to the MEDICAL RECORD (July 30, 1910), the Pfannenstill method claims to derive its therapeutical effect from the development of iodine in *statu nascendi* in the tissues, a development brought about by the administration of sodium iodide per os and the local application on the affected parts of hydrogen peroxide or of ozone.

Dr. Strandberg's modification of the method for treatment of lupus of the nasal mucous membrane is as follows: As soon as the diagnosis is secured the patient begins taking six daily doses of sodium iodide 3 grains, increasing in four to five days to six daily doses of 9 grains. Meanwhile the interior of the nose is cleansed from scabs by the application of cotton wool swabs with 1 to 2 per cent. alsol-dermofil. The swabs are left in the nose during night time. Thereafter the specific treatment begins, consisting in the packing twice daily of the nasal cavities with swabs of boiled gauze (free from starch) moistened with a solution of 3 per cent. hydrogen peroxide, to which is added ferric chloride (Fe Cl3) and hydrochloric acid in order to increase the oxidizing power of the solution. A bottle of this solution is also given to the patient, who is obliged to participate very actively in the treatment, instilling every ten minutes a quantity of the solution on to the nasal packing, until he feels the solution entering the nasopharynx. Meanwhile the internal administration of sodium iodide is continued. After some days of this treatment the nasal mucous membrane is seen to be more ulcerated and hyperemic than before the beginning of the treatment. If this is not the case, or if some of the ulcerations have already healed up, then either the doses of natrium iodide have been too small or the hydrogen peroxide has not been applied in sufficient quantities to the nasal packing. In the last-mentioned cases it is therefore necessary to increase the doses of natrium iodide and to instruct the patient about the necessity of instilling the hydrogen peroxide solution assiduously on to the nasal packing. If, however, the ulcerated state of the interior of the nose is accentuated, a new phase of the treatment sets in. The nasal packing, changed twice daily, is now moistened with a solution of hydrogen peroxide 3 per cent. and acetic acid 1 per cent.; the solution given to the patient for self-application is weaker, hydrogen peroxide 1 per cent. with acetic acid ½ per cent.

After six or eight weeks' treatment the granulations disappear and the ulcerations heal up; sometimes, however, an ulceration may not become covered with epithelium in spite of prolonged treatment. The reason seems to be that the ulceration is continuously irritated by the excretion of iodine, as upon the lessening or discontinuing of the doses of natrium iodide the ulceration may heal up in twenty-four hours. The treatment ought not to be discontinued before the infiltration of the tissues has totally disappeared. An after treatment is then begun, consisting of the application of alsodermofil 1 per cent. to 1½ per cent., when after a short time the mucous membrane assumes first a normal, subsequently a somewhat paler coloring. If this point has been reached a relapse is improbable. It is essential to the success of the treatment that it be the medical man who changes the packing of the nose twice daily, as the packing must be in actual contact with all affected parts of the mucous membrane, and neither too firmly nor too loosely applied. The packing must remain in the nose during the night, as otherwise scabs are sure to form and the treatment will become with-

out effect until the scabs are removed. That is also why it is contraindicated to use the galvanocautery or chemical caustics during the treatment. The duration of the treatment can be estimated as between two and three months. If this time is not available it is certainly preferable not to begin the treatment.

The number of patients treated by Dr. Strandberg is 104, among whom many inveterate cases, *e. g.* one of twenty years' standing. Without going into details, the results may be said to be surprisingly good, considering what has hitherto been obtained by the usual methods. Cases of lupus of the palate and the tongue have also been successfully treated by suitable modifications of the method.

It is well known that equally favorable results have been obtained by other Scandinavian physicians in cases of lupus of the mucous membrane. On the other hand it seems as yet uncertain whether the Pfannenstill method will prove of similar efficiency in the treatment of laryngeal tuberculosis, which was looked forward to after the publication of the first cases of this disease treated by Dr. Pfannenstill.

Coexistent Epidemic Cerebrospinal Meningitis and Malaria. W. J. Collins.

Ether Anesthesia.—D. F. Mahoney describes his method of administering ether. The active purging of patients before operation is discouraged. Twenty minutes before the administration of the anesthetic the patient is given subcutaneously ⅛ of a grain of morphine and 1/120 of a grain of atropine. In the case of children atropine in doses of 1/240 to 1/150 of a grain is administered alone. The drop method of administering ether is satisfactory in many cases, but in alcoholic and highly nervous patients, in athletes, and in patients of large stature the use of the cone is preferable. If there is asphyxia due to nasal obstruction, the author recommends the use of two pieces of soft rubber tubing, each six inches long, which are lubricated and introduced into the nostrils along the floor of the nose.

Anesthesia.—F. Allen states that all operations that can be so performed should be done under local anesthesia. It is desirable to more or less thoroughly narcotize a patient who is about to receive a general anesthetic. Spinal anesthesia by means of tropacocaine and adrenalin is an exceedingly safe procedure. Gas and oxygen form a very valuable and in some cases almost ideal anesthetic, but they should always be administered by an expert anesthetist.

Nitrous Oxide and Oxygen Anesthesia.—A. H. Mandell maintains that the advantages of nitrous oxide over ether are distinct, and may be clearly evidenced by the following facts: the patient loses consciousness in three or four breaths; he has no strangling or choking; he recovers consciousness immediately when the anesthetic is stopped; he has little, usually no, nausea or vomiting; he can take liquids much sooner after operation; his ultimate recovery is hastened.

Intratracheal Insufflation Anesthesia.—W. C. Quinby notes that the essential features in which this method differs from ordinary anesthesia with a cone are that by means of a tube passed into the trachea, and fitting it loosely, ether-laden air is delivered at or just above the bifurcation of the trachea in a nearly constant stream from a bellows or other source. When this is done there follows a very important phenomenon. The to-and-fro respiratory movements become markedly fewer in number, until, with a sufficiently large volume of air sent through the tube, respiratory movement ceases entirely. The heart-beat and blood-pressure, however, continue in a perfectly normal manner, practically unaltered. In other words, a condition has been produced in which the usual to-and-fro respiratory movements are no longer necessary for maintenance of life, and in which the surgical entrance to either one or both sides of the thorax is possible, without the occurrence of any ill-effects from the ensuing pneumothorax. The first and most important advantage of intratracheal insufflation is found in its use during surgical operations which open the chest cavity, for, in contradistinction to all other methods yet used, this is the only one in which proper oxygenation of the blood is performed independently of any respiratory effort on the part of the patient.

Apparatus for Intrathoracic Insufflation.—A. Ehrenfried describes an apparatus that he has devised for the administration of ether by the intrathoracic insufflation method.

Hints on General Anesthesia.—R. W. Hornabrook states that any class of case can be put under with open ethyl chloride and ether and the state of anesthesia can be regulated if necessary by chloroform, but the mask must be of an open nature, must fit well, and the patient must breathe through it. Of the different masks, Murray's is the best and fits nearly all cases; should it not fit, then one may use a towel of open character, fairly heavy in material.

Anesthesia.—W. M. Boothby presents a brief account of the history of anesthesia.

The Management of Spinal Curves.—E. H. Bradford describes the various preventive, gymnastic, and corrective measures to be used in the treatment of spinal curvature.

Meningitis and Malaria.—W. J. Collins reports three cases of epidemic cerebrospinal meningitis, one of tertian malaria, and one of cerebrospinal meningitis coexisting with tertian malaria. The five cases came from the same locality in Lamia, Greece.

Treatment of Fracture of the Shaft of the Femur. J. Douglas and J. N. Drury.
Report of a Case of Aneurysm of the Thoracic Aorta Treated by Abram's Method. L. C. Boyd.

Experimental Poliomyelitis Transmitted by Dust.—M. Neustaedler and W. C. Thro present a further contribution on this subject and conclude that poliomyelitis is propagated by dust, that the nasopharynx is probably the point of entry, and that acute poliomyelitis is both infectious and contagious.

Salvarsan.—G. F. Lydston is convinced of the great value of salvarsan in meeting the following indications: (1) Prompt removal of severe genital lesions, thus lessening, first, the danger of infecting others; second, the danger of detection; third, local discomfort; fourth, the danger of serious local complications of a destructive character. (2) The prevention or prompt removal of disfiguring skin lesions. (3) Precocious or malignant syphilis and obstinate destructive bone and cartilage lesions, especially of the face and nose. (4) Cases resistant to or intolerant

of mercury. In this class of cases salvarsan is often of inestimable service. (5) Early nerve and brain and all visceral lesions, with the exception of renal syphilis, in which salvarsan is especially dangerous. In late lesions of the nervous system its use may occasionally be justifiable. (6) Cases of syphilitic cachexia or anemia, which often consist of a combination of overtreatment and syphilis. (7) Severe and rapidly destructive lesions of the throat and obstinate lesions of the tongue. (8) Syphilis involving the organs of special sense, excepting lesions involving the retina. (9) Early tabes or exceptionally in late—not terminal—cases in the hope of relieving severe pain or involvement of the sphincters. (10) Infantile syphilis.

Syphilis of Anorectal Region.—L. H. Adler emphasizes the fact that cases of primary and secondary syphilis are frequently found, showing no visible evidences of the disease, except at the anus, and in rare instances within the rectum. In order, therefore, to clear up any doubtful case, an inspection of the anorectal region should be made. The result of such investigation will often surprise the uninitiated.

Acid and Alkaline Salvarsan Solutions.—G. M. MacKee states that the use of concentrated acid solutions of salvarsan will almost surely cause death. Weak (0.1 per cent.) acid solutions of salvarsan can be given apparently with absolute safety in individuals who present no contraindications to salvarsan. With the exception of the absence of a local reaction, when some of the fluid enters the subcutaneous tissue, it is doubtful if there is any advantage in the administration of the acid solution.

Salvarsan and the Eye and Ear.—F. P. Hoover believes that injections of salvarsan will produce not only a neuritis of the optic and auditory nerves, but will also produce or augment labyrinthine disease. He reports a case presenting labyrinthine disease, which was not developed sufficiently to be noticed by the patient and which was augmented by the use of the salvarsan.

Aural Complications of the Exanthemata.—T. L. Saunders states that the keynote to the true conservative management of the aural complications of these diseases rests on two points: first, the recognition of their too frequently insidious onset by daily aural examinations, and, second, the necessity for their prompt and energetic treatment by early incision of the drum membrane, followed, when indicated, by an early mastoid operation.

Tuberculosis of Ears.—J. S. Cipes reports a case of tuberculosis of both ears cured by tuberculin.

Fracture of the Femur.—J. Douglas and J. N. Drury describe a new traction splint for the treatment of fracture of the shaft of the femur.

Aortic Aneurysm.—L. C. Boyd reports a case of this condition apparently successfully treated by means of Abram's method of concussion of the seventh cervical vertebra.

Treatment of the Arthritides.—L. Litchfield notes that, exclusive of trophic, hemophilic, traumatic, and certain septic cases, the arthritides may be divided into three classes—rheumatic fever, gout, and hypotrophic and hypertrophic arthritis. Gout is due to the abnormal accumulation of uric acid in the system, and this acid is not now regarded as a stage in the production of urea, but as a natural end product of purin metabolism and resulting about equally from endogenous and exogenous sources. What is called rheumatic fever or rheumatism, etc., is a general infection and the diseases commonly called arthritis deformans and rheumatoid arthritis, whether regarded as different diseases or as manifestation of the same one, are not closely related physiologically either to gout or rheumatic fever. The only agent that has been scientifically proved to increase materially the elimination of uric acid, without correspondingly increasing its production, is radioactivity. There is no such thing as an antirheumatic diet, but all patients except the gouty should be nourished as generously as their digestion will permit. Many cases of arthritis are unfavorably affected by septic foci, such as pyorrhea, antral and sinus disease, etc., and in certain cases these may be the points of entry of the disease germs or toxins causing the disorder. There is abundant evidence that salicylic acid is specific for rheumatic fever, and for that alone. The combination of alkalies with salicylic acid is supported by statistical evidence and is not contraindicated. In chronic arthritis or arthritis deformans the chief indication is to give the best possible nutrition, to prescribe outdoor life, and rest, and to build up the bodily reserve forces.

Experimental Intestinal Obstruction.—By J. W. Draper. (See MEDICAL RECORD, July 8, 1911, page 97.)

Solid Culture Media.—A. J. Bendick describes a formula for the preparation of solid media in which by the addition of calcium carbonate the differentiation of sugar-fermenting bacteria, especially of the colon-typhoid type, is facilitated.

Pinning Fractures.—By R. T. Morris. (See MEDICAL RECORD, July 8, 1911, page 101.)

Lane's Plates in Treatment of Fractures.—By W. Bartlett and W. R. Hewitt. (See MEDICAL RECORD, July 8, 1911, page 101.)

Thirty Years' Experience with Fractures.—By R. W. Corwin. (See MEDICAL RECORD, July 8, 1911, page 101.)

Open Treatment of Fractures.—By E. Martin. (See MEDICAL RECORD, July 8, 1911, page 101.)

Clinical Thermometers and Infection.—E. B. Beasley has performed a series of experiments to test the power of the clinical thermometer in carrying infection. The results showed that this power is a real one. A thermometer may retain live bacteria—capable of being recovered—after the thermometer is fairly well washed, dried and then placed in the case for three hours. It would seem necessary that physicians should keep their thermometers immersed in a true disinfectant if they would eliminate this source of danger to their patients. Formaldehyde solution would be the best as, like carbolic acid, it does not damage the etchings of the thermometer.

Postoperative Treatment.—S. T. Pope criticises certain traditions in the treatment of postoperative cases, such as the food withdrawal before operation, the withholding of water after operation, postoperative purgation, etc. The starvation has often developed a fatal acidosis and beef tea or malted milk has been given when one should have used carbohydrates and alkalies. After all general anesthesias it is a good procedure to let the patient drink repeatedly, at intervals, a glass of water containing a dram of sodium bicarbonate. If this is vomited it is a good gastric lavage; if retained it tends to forestall acid intoxication. The author ridicules the fear of constipation after operation and the use of depressant cathartics. The colon tube should be abandoned as of no use; a simple rectal enema will suffice. Morphine does not favor the production of ileus. Conservative measures, such as constriction

of the extremities, are better than flooding the system with water. In simple collapse no drugs are indicated and moderate hemorrhage causing fall of blood-pressure is probably conservative as tending to produce hemostasis and coagulation. The vasomotor system will readjust its physiological balance itself if given time. In every case demanding catheterization hexamethylenamine should be given in sufficient doses to prevent an ascending infection from cystitis and the value of the remedy in infections of the meninges, gall-bladder, and serous cavities in general should be sufficient to prompt the employment of this drug.

Mobility of the Heart.—By D. Fulton. (See MEDICAL RECORD, July 8, 1911, page 98.)

Bacteriology of the Ear.—J. Hudson concludes that bacteria are normally present in the mastoid antrum, that mastoiditis may be caused by a variety of organisms, and that the few patients whom he treated with vaccines after operation were greatly benefited.

The Past Work of the Obstetrical Society of London, and the Obstetric and Gynecological Problems Still Awaiting Solution. A Routh.
Intracranial Murmurs in Their Relationship to Tinnitus Aurium. T. B. Hyslop.
Intestinal Hemorrhage in Typhoid Fever and Its Relation to the Agglutinating Power of the Blood. H. Whitehead.
Acute Middle Ear and Mastoid Inflammations; The Relations of Active Autointoxications. S. F. Snow.
The Ophthalmo-Reaction of Calmette in the Early Diagnosis of Phthisis. A. Stroud Hosford.
Researches in Epilepsy. D. Moore Alexander.

Obstetrical and Gynecological Problems.—A. Routh states that the mortality both *in utero* and soon after birth is still far larger than it should be. The accoucheur is responsible for the newborn child, during at all events the first fortnight of life, and in that period nearly one-third of those children who do not survive their first year lose their lives. Progress in the knowledge of the physiology of menstruation, labor, and lactation, and of the causation of the toxic diseases of pregnancy and the puerperium, will not be possible without the aid of the physiological chemist. Obstetricians are still ignorant of the biochemical changes in the blood which influence the cyclical functions of menstruation and ovulation, or which have to do with the implantation of the fertilized ovum and the onset of labor and lactation. Little is known also of the autotoxemias lying at the basis of pernicious vomiting, puerperal albuminuria, eclampsia, chorea gravidarum, and puerperal insanity. The blood serum of pregnant women hinders the proteolytic ferments, as trypsin, while placental serum has a marked power in destroying cancer cells. Pregnant women have a relative immunity to scarlet fever. Excess of lutein tissue is associated with hydatidiform degeneration of the chorion, while destruction of the lutein tissue prevents implantation of the ovum. Abnormalities in the menstrual function are associated with diseases of the ductless glands. The following gynecological questions await solution: When should a pyosalpinx be operated upon and when left alone? What is the pathology of fibrosis of the uterus? What is the explanation of menorrhagia of puberty? Of what use is the retention of the term "endometritis" when used for adenomatous overgrowths of the uterine mucosa and what is the cause of vascular caruncle of the urethra? The author is opposed to operating on a fibroid that is producing no symptoms. He believes that one is at the beginning of a period when other methods of treatment than surgery are gradually being resorted to for many gynecological conditions that have hitherto been regarded as distinctly surgical.

Intracranial Murmurs in Relation to Tinnitus Aurium.—T. B. Hyslop states that there are three different kinds of brain movements: (1) pulsatile movements communicated from the pulsations of the large basal cerebral vessels; (2) respiratory movements, in which the brain rises during expiration and falls during inspiration; and (3) vascular elevations and depressions which alternate and are due to periodic dilatation and contraction of the blood-vessels. It is in connection with one or other of these movements that sound vibrations are apt to occur in the arterial, venous, or lymphatic systems. During these movements the cerebrospinal fluid is subjected to compensatory movement. When there is great expansion of the cerebral volume, owing to arterial pressure, and the cerebrospinal fluid has been driven out of the cranium, the brain comes into contact with the rigid bone, and, as a consequence, any murmur which becomes audible, either subjectively or on auscultation, is nearly always pulsatile The high arterial pressure which occurs in Bright's disease is attended by undue pressure on the peri- and endolymph and gives rise to tinnitus. In hemicrania due to gout the intracranial arteries may be dilated or hyperextended, and by their more forcible action not only drive the cerebrospinal fluid from the cranial cavity causing increased tension in the labyrinth, but, by the same process, force the brain toward the internal table of the skull and thereby render it possible for the pulsatile waves to come into almost direct contact with it. So it is in conditions of plethora culminating in apoplexy, of which tinnitus is an early symptom. Tinnitus is often a prominent and distressing symptom in anemia and chlorosis. Venous murmurs may be of pulsatile or respiratory rhythm. Various intracranial murmurs are also produced in many cases of cerebral aneurysm.

Intestinal Hemorrhage in Typhoid Fever.—H. Whitehead concludes that intestinal hemorrhage gives rise to an increased formation of agglutinins in the blood lasting for a short time, which may help to tide the patient safely over a dangerous period. As a result of his investigations he recommends that, in many toxic cases of typhoid fever, and more especially in those in which the blood gives a poor agglutination reaction, phlebotomy to the extent of about 10 ounces (according to the physical condition of the patient) be tried as a treatment. It would in all probability give excellent results in many cases, as it would be without the accompanying dangers of intestinal hemorrhage.

Middle Ear and Mastoid Inflammations.—S. F. Snow believes that these should be attacked not merely by means of local measures. Constitutional treatment is also necessary. There are certain alteratives that can cause the blood to become bacteriolytic; certain medicines that seem to act as antigens and induce the formation of more antibodies, or at least rehabilitate them with more antitoxic power. Any substance capable of inciting the formation of antibodies is an antigen. Mercury, iodine, the adrenal extractives, etc., seem to be in this class and are hopeful adjuncts in the fight against disease. Vaccine therapy also holds out some hope in the subacute and chonic cases, but the indications are not very encouraging in cases of acute mastoid trouble. The author relies at present most upon mercury by the mouth in some form as a remedial agent.

Calmette Reaction in Tuberculosis.—H. Stroud Hosford concludes that a negative result by no means excludes pulmonary tuberculosis. Some very advanced cases fail to give a reaction. He has never obtained a positive result except in true cases. He has never seen any bad results whatever from the use of the test as regards the eye. If a patient in a suspicious case fails to give a reaction, then the test should be applied on three different occasions, with an interval between each application of from three to four weeks.

Researches in Epilepsy.—D. Moore Alexander points out the fact that there appears to be a relationship between an epileptic fit and a low urea-ammonia ratio.

Auricular Fibrillation. By J. Mackenzie.
Aspects of Medicine as a Profession. J. T. J. Morrison.
A Large Fibrocystic Tumor Distending the Buttock. J. D. Malcolm.
Congenital Diaphragmatic Hernia Associated with Embryonic Organs. L. Rawes.

Auricular Fibrillation.—J. Mackenzie states that 60 or 70 per cent. of all cases of serious heart failure met with in practice owe the failure directly to this condition or have the failure aggravated by its presence. The most common evidence of this condition is an irregular action of the heart of a very disorderly kind. While senile and rheumatic hearts are those most frequently affected by this condition, there are numerous cases in which auricular fibrillation occurs, where there is no history of rheumatism, and at an age when senile changes are not present in a marked degree. Auricular fibrillation is present in the great majority of cases with dropsy, or dyspnea due to heart failure, where there is an irregular pulse. The term "fibrillation" is applied to a curious condition of the muscle fibers of the heart, where the individual fibers, in place of contracting in an orderly and simultaneous manner during systole, contract rapidly and independently of one another. The auricle, when in a state of fibrillation, presents an entirely different aspect from what it does during its normal action. Experimentally auricular fibrillation can be produced by electrical stimulation of the auricular wall. In the human heart it is found to arise under a variety of conditions. It is probable that it is produced by altered nutrition of the muscle. Effort, sometimes slight and simetimes violent, may provoke auricular fibrillation. This occurs most frequently in the middle-aged or elderly. In hearts which have shown auricular fibrillation during life there has been found in the auricle and ventricle an increase of fibrous tissue and of nucleated cells in the muscular walls. In the majority of cases when auricular fibrillation sets in it persists for the remainder of the individual's life. When the auricle passes into fibrillation the ventricle usually becomes irregular in its action. A considerable enlargement of the heart follows the inception of auricular fibrillation, which also increases the impairment of the heart. Cases of fibrillation stand apart from all others in regard to their response to the action of digitalis. With only rare exceptions all the cases that show a marked effect upon the heart are cases of auricular fibrillation, for although other cases might exhibit some benefit from the use of the drug, they never show the same tendency to slowing of the heart's rate. The slowing effects of digitalis are shown in a very striking manner in those cases of auricular fibrillation where heart failure sets in with a great increase of rate of the heart.

Medicine as a Profession.—J. T. J. Morrison discusses the following topics in medical sociology: the life history of the medical profession in England; its relation to legislation; and the question of medicine and public practice. The first Medical Act legalizing the practice of medicine in England was passed in 1511. It provided for a board consisting of medical and surgical examiners presided over by a bishop. The Royal College of Physicians was founded in 1518. Barber surgery was initiated by the exclusion of the clergy from surgical practice on the ground that effusion of blood was repugnant to the Church. Into the field thus abandoned entered the lay servitors, a class more or less trained as assistants to the surgical monks, and expert in such feats of minor surgery as venesection. Medieval trade unionism found expression in the formation of guilds, and in due course the London barber surgeons were federated as a special section of the barbers' guild. Commencing as a section of the Grocers' Company, the London apothecaries were raised to the dignity of an autonymous company by a charter of James I. The Apothecaries Act was passed in 1815; it created a new grade of medical practitioner neither physician nor surgeon. The Medical Act of 1858, creating a general medical council with large powers of regulation and discipline, is still in force. The author reviews the development of public practice in England and notes that there is a progressive tendency on the part of governments to utilize the service of medical practitioners for national purposes.

Fibrocystic Tumor.—J. D. Malcolm reports a case of an enormous fibrocystic tumor distending the buttock in a woman aged 30. This tumor was an extension along fascial planes of cystic tumors behind the uterus and beside the vagina.

Diaphragmatic Hernia.—L. Rawes reports a case of this condition associated with underdevelopment of the various organs in a newborn infant. Death occurred twenty hours after birth.

Münchener medizinische Wochenschrift.

October 10, 1911.

Alimentary Fever in Adults.—Walterhöfer refers to the classic work of Finkelstein in connection with alimentary fever in nurslings. In affections of the alimentary canal both sugar and salt can cause rise of temperature. The earlier attempts to produce the same phenomenon in adults resulted negatively, even when the sugar and salt were injected subcutaneously. Nevertheless alimentary fever does occur in certain subjects under certain conditions. The author narrates the case of a patient with gastroenteric symptoms, chiefly subjective, who developed fever as a result of eating certain articles of food. The fever seemed to coincide with the supervention of pain and nausea. A study of the diet showed that sugar and salt were responsible for the symptoms. Diet fevers probably represent an anaphylactic reaction. After a period of dietetic supervision the intolerance to these substances disappeared for the time. Egg albumin was then tested and the ingestion of raw eggs caused a temperature rise of 40.6° C. The patient had never partaken of eggs in the raw state, having always had a marked distaste for them. It was thought possible that the fever was hysterical and due to certain flavors operating by suggestion. Saccharine, however, failed to produce temperature rise. The case was studied exhaustively for five months and the author concluded that, while some dietetic articles were notably pyretogenetic, no sharp line could be drawn between these and other articles, for these might sometimes set up fever.

Acetonuria in Diphtheria and Acute Anginas.—Reiche speaks of the conflicting statements of authors concerning this subject. While some would use the occurrence of acetonuria to exclude diphtheria, others find the two conditions in frequent association. The author has therefore tested the immense material in the Hamburg-Eppendorf Hospital in the hope of clearing up the obscurity. In a series of over 3,000 cases of diphtheria acetonuria was present in 65 per cent. In all other forms of acute angina the percentage of acetonuria was about 40. The only diagnostic significance attributable is the possibility of differentiating diphtheria from the mildest form of angina, the presence of acetonuria suggesting diphtheria.

Specific Treatment of Gonorrhea.—Schmitt refers to the treatment of all forms of gonorrhea with improved vaccines. He has obtained good results in epididymitis, in many cases of gonorrhea of the cervix, and in the vulvovaginitis of children. He thinks it probable that gonorrheal prostatitis and spermatocystitis are amenable to the vaccine treatment. He could not satisfy himself that the latter possessed any bactericidal potency in urethral gonorrhea, while in arthritis the only result noticeable was diminished pain. The only unpleasant collateral effects were occasional temperature rise and headache. Probably the most significant property of the vaccine is its power over many cases of cervical gonorrhea.

Insurance Medicine.

SUGGESTIONS TO MEDICAL EXAMINERS.

BY THE INSURANCE EDITOR.

PERSONAL HISTORY.

Circulatory System.—The personal history in regard to diseases of the circulatory system is usually meager for the reason that an applicant who understands that he has a heart murmur or diseased arteries is not likely to apply to a company that does not issue substandard policies. The majority of applicants in whom these conditions are discovered at the examination learn of them then for the first time. Occasionally, however, some person will apply who has previously been rejected and has learned that this action was taken on account of a heart murmur. He may admit this and at the same time declare that he has been examined since by his attending physician or some other doctor and found free from any indications of heart disease. He naturally believes in the more favorable diagnosis and, for this reason, feels justified sometimes in omitting the statement that any trouble was ever found with his heart. It is a good idea to question every applicant closely as to whether he has ever been refused the kind of insurance he applied for and, if he has, to ascertain the cause when possible. If he admits it was heart trouble or does not know, the heart should be examined even more carefully than usual during rest and also after he has been put through some form of exercise.

While, then, the previous history of defects in the circulatory system will not prove important in most cases and reliance for discovery of them must be largely based upon the physical examination, it is essential to question the applicant in regard to the following conditions:

Palpitation, Irregularity, Intermittency.—Ascertain the date, duration, and cause of each attack. Whenever an applicant acknowledges a history of one or the other of these disturbances, the heart should be thoroughly examined both during rest and immediately after some form of exercise to determine its size and location and whether there is a murmur.

Experience has convinced many physicians interested in life insurance that a persistently irregular or intermittent heart action does not detract from the insurability of a risk when the applicant is under 40 years of age, has not indulged in the excessive use of alcohol, is not an overweight, and all heart lesions have been excluded after a careful reexamination. Moreover, a heart action slightly over 90, the maximum rate commonly adopted by the companies, is not seriously considered in one who also is within the normal limits of weight, under 40 years of age, and has not used too much alcohol; but in these cases a careful reexamination of *all* the organs is required in order that the examiner may assure the company that the rapidity is not excited by some pathological condition. A full history in both these classes of cases should be always furnished, even though no abnormality is discovered in the examination. When no focus of irritation is found to account for the irregular, intermittent, or rapid heart action in these applicants, it may be set down as an idosyncrasy, probably the overflow of a rather active nervous system. If it is learned after a searching inquiry that the disturbance of the heart action was transitory and undoubtedly due to some unusual exercise, the fact is not worth recording.

Dyspnea.—A history of difficulty in breathing due to pulmonary congestion is sometimes obtained when the applicant has been subject to heart disease. The chief importance of the symptom will be to emphasize the gravity of the disease, as a lesion extensive enough to cause this disturbance will be easily recognized during the physical examination.

Pain in Region of Heart.—Give date, duration, severity, and cause of each attack. Close questioning will bring out the fact that the pain was caused by intercostal neuralgia in many of the cases, but the examiner is reminded that intercostal neuralgia is often given as the origin of pain in the chest when the real cause was pleurisy or angina pectoris.

Acute Rheumatism.—Whenever a history of this disease is obtained the examiner should endeavor to learn whether there was any form of involvement of the heart during or immediately after the attack. The date of the attack of rheumatism, the nature of the cardiac trouble, and the date of its last manifestation will be required.

Dropsy.—Ascertain the date, duration, cause, and parts affected. The dropsy may have followed malaria, some fever, or acute disease of one of the organs, in which case the risk will usually be acceptable if sufficient time has elapsed since full recovery. If, however, it occurred as a result of some form of heart disease the risk will not be accepted.

Purpura Hemorrhagia.—A history of this condition is always ground for rejection, as it is liable to be accompanied sooner or later by dangerous internal hemorrhages as well as effusions of blood under the mucous membranes. It is highly important to learn whether the applicant is a "bleeder," when he gives a history of nose bleeding, prolonged bleeding after extraction of teeth, or bleeding from the gums.

Anemia.—Ascertain the date, duration, and cause. In most of the cases it will have been due to some passing cause which does not detract from the value of the risk after full recovery. On the other hand, an investigation may bring out the fact that it was due to a chronic constitutional disease such as nephritis, pulmonary tuberculosis, or syphilis.

Varicose Veins.—An applicant with extensive varicose veins should be rejected. When the varicosities have not recently progressed rapidly, are not too marked or extensive, and are helped by the use of an elastic stocking, they may be accepted provided the history is one in which the occurrence of large or frequent ulcerations does not enter.

The Healed Tuberculous Lesion from a Life Insurance Standpoint.—By George Parker, M.D. (See page 915.)

Contusions of the Abdomen.—Dr. Richard V. Hippel opens a lengthy article on this subject by quoting de Suervain, who says in contusions of the abdomen rapid diagnosis as to the condition of the intestines must be made. Peritonitis frequently appears while doubt is entertained whether the intestines are wounded or not. This remark applies especially to wounds of the abdomen made by dull weapons and not resulting in perforation of the parietes: the latter case should be treated surgically from the beginning. The force causing contusion of the abdomen may act on a circumscribed area or be diffused. The kick of a horse, a blow with a hammer, etc., belong to the

first class of injury; a fall from a height, "Cuffer" accidents, etc., illustrate the second variety. Women are rarely exposed to either variety of injury; children, however, are frequently injured so far as the abdomen is concerned by being run over while at play. Injuries of the stomach and intestines are usually produced by a circumscribed force, a "spreading" force frequently resulting in injuries of parenchymatous organs. Two dangers are present in either case: hemorrhage and escape of infectious material into the peritoneal cavity. Severe hemorrhages are usually due to injury of the liver or spleen; these are usually fatal unless quick surgical treatment is adopted. Out of 165 cases of injury of the liver 150 ended fatally because of the primary hemorrhage. The value of immediate operation is shown by another set of figures, thirty-two patients out of eighty with injuries being saved. Injuries of the spleen show even a better percentage of recoveries. Injuries of the mesentery are seldom accompanied by severe hemorrhage as the line of injury usually runs parallel to the large vessels. Infection is the constant danger in injuries of the intestines, especially as multiple perforations are very frequent. Early operation even here has reduced the mortality from one hundred to twenty-three per cent. in the last twenty-five years. Most chance of success is present if operation is performed within the first six hours after injury. Rupture of the bile ducts may be accompanied by immediate infection or by an "irritation peritonitis." Operation has given eighty-eight per cent. recoveries, while of the non-operated cases only twenty-two per cent. recovered. Rupture of the urinary passages is accompanied by a high mortality which has been only a little diminished by early operative interference. The general conclusion, then, is: as soon as traumatic rupture of intraabdominal organs has been diagnosed, operation should take place. Diagnosis of the condition is, therefore, the most important thing. There are, however, no certain and pathognomonic symptoms, but there are many important phenomena that point to the right conclusion.

Many organs may be injured at the same time; examination, therefore, should embrace all intra-abdominal viscera. Shock is the first symptom of contusion of the abdomen, being due to injury of the vagus, splanchnic nerves, or the solar ganglion. It may result in immediate death. At other times, it leads to prolonged unconsciousness, and in general is proportionate to the severity of the injury. Spontaneous pain is at first localized at the site of injury, but soon spreads. It may result in a characteristic attitude, a dorsal decubitus with knees drawn up being adopted by the patient. Pain, however, may be completely absent, and likewise abdominal respiration, which when noted is a valuable sign. Initial vomiting is without significance, unless much blood is brought up, when injury of the stomach may, of course, be considered probable. Vomiting in the early hours after injury is more important; it is usually absent if contusion alone has taken place, but is frequently noted, alternating with nausea, if the hollow viscera are injured. This symptom, however, may fail completely until general peritonitis has developed. A rise of temperature is of little significance for early diagnosis; it may be subnormal in the period of shock. Pulse rate is important; if it rises after shock is gone, it means severe injury and a bad prognosis. Local symptoms consist in tenderness and rigidity, both being signs of peritoneal irritation, which may be caused by non-infectious or infectious material. Yet rigidity may be totally absent, or may be very evident when extraperitoneal organs are at fault. Injuries of the kidney and inflammations of the lungs may lead to very deceptive rigidity of the abdominal walls. Severe hemorrhage into the abdominal cavity is often accompanied by a very clear clinical picture. Primary shock is followed by a temporary recovery, which gives place to rapidly progressing collapse. Acute anemia becomes apparent at the same time. The liver should always be suspected, because of its vascularity, when such symptoms are present. —*Zeitschrift für Versicherungsmedizin*, August, 1911.

Diseases of Household Servants in Comparison with Those of Other Workers.—The Vienna correspondent of the *Journal of the American Medical Association* writes that a union of household servants is being formed in Austria. One of the earliest results of the movement is the information obtained in regard to the distribution of disease among this part of the population. Hitherto the conditions have been regarded by some as favorable, while others have thought them very bad. Certain affections are very frequent. Thus in Vienna anemia, disorders of the stomach, rheumatism, and troubles of the sexual organs are the most frequent, in the order mentioned. Anemia is readily explained by the long stay in badly ventilated rooms and the rare walks in fresh air, as well as by the insufficient amount of sleep; sometimes the quantity of food is insufficient. Cooks suffer from gastric disorders because of the too frequent tasting of the foods they are preparing. Rheumatic affections are very common among all servants, partly on account of the frequent exposure to cold and bad weather, without sufficient protection; partly from working in unhealthy kitchens, washing kitchens and sculleries. A frequent complaint of servants is static flat-foot with varicose veins of the legs. Affections of the lungs are less frequent than one would expect in Vienna. It seems that the inherited constitutions of the servants—mostly women from the healthy rural districts—protect them to a great extent; their health statistics are much better than those of, for instance, shop assistants, typewriters, and office girls. The reports of the Vienna Krankenkasse concerning the latter group show that within one year more than 13 per cent. of the members have suffered from affections of the respiratory organs, lasting more than three days, while for house servants the figures are found to be about half of that. The alimentary canal was affected in 9 per cent. of the latter, while in 11 per cent. of the shop and office girls the conditions of nourishment were also decidedly in favor of the house servants. Worst off is the factory girl, who not only is often underfed but is also exposed to much more danger of physical and moral nature. Illegitimate births are most frequent among this class of workers; the house servants come next in this respect, while the third group only rarely contributes to this item. A remarkable fact is the relative frequency of nervous diseases and neurasthenia, or rather hysteria, among the housemaids; one would not suppose that fully 2 per cent. of all the servants in this group are classified as victims of such diseases. Surgical diseases, except panaritium, bursitis patellaris, and dental periostitis, are not frequent among servants, while the factory girls are prone to various factory accidents.

The Motive for Taking Out Insurance.—E. J. Spratling said that the exact motive for taking out insurance, if known in every case, would give the exact percentage of risk incurred by the company. The four principal motives are protection of family, fair or unfair, protection of business, fair or unfair, investment and speculation. Unfair protection has fear behind it as a motive and results in bad risks for the company; such is the insurance taken by a man who somehow suspects illness which can be concealed and yet shorten life materially. Protection of business is frequently unfair when it is of "joint life" kind. Insurance for investment is usually safe for the company but is almost obsolete. Speculative motive should be suspected, if no other motive is plainly seen.—*Proceedings of the Medical Section, American Life Convention, New Orleans*, February, 1911.

Book Reviews.

Yellow Fever and Its Prevention. A Manual for Medical Students and Practitioners. By Sir Rubert W. Boyce, M.B., F.R.S., Holt Professor of Pathology, University of Liverpool; Dean of the Liverpool School of Tropical Medicine; Commander of the Order of Leopold III; Fellow of University College, London; Bacteriologist and one of the Public Analysts to the City of Liverpool. With Illustrations. Price $3.50. New York: E. P. Dutton & Company, 1911.

The late Professor Boyce had completed this volume just before his death. It presents a summary of his experiences and investigations in New Orleans early in 1905, in British Honduras and Central America late in 1905, in Barbadoes and other islands of the West Indies and British Guiana in 1909, and in West Africa in 1910. The subject is treated historically, geographically, and from the viewpoint of symptomatology, treatment, pathology, diagnosis, epidemiology, entomology, and prophylaxis. This book is the result of first-hand study of yellow fever in different parts of the world. The author devoted the last years of his life to a careful investigation of yellow fever on the West Coast of Africa, and special stress is laid in this volume upon the existence of yellow fever in this region. He has found that from time immemorial yellow fever has been endemic in West Africa. Many cases of so-called bilious remittent fever and of other fevers have been really cases of yellow fever. In fact, it is suggested that the evidence would seem to indicate that the home of yellow fever may be, after all, West Africa, and not the New World.

A Manual of Practical Hygiene. For Students, Physicians, and Health Officers. By Charles Harrington, M.D., late Professor of Hygiene in the Medical School of Harvard University. Fourth Edition, Revised and Enlarged by Mark W. Richardson, M.D., Secretary to State Board of Health of Massachusetts. Octavo, 850 pages, with 124 engravings and 12 full-page plates, in colors and monochrome. Price $4.50. Philadelphia and New York: Lea & Febiger, 1911.

The growing importance of preventive medicine creates a special demand for authoritative works on practical hygiene, to which category the present volume belongs. The untimely death of the author occurred while he was engaged on a revision of this work; nevertheless this revision has been ably completed by his successor on the State Board of Health of Massachusetts. It is hardly necessary to point out, as has been done in the case of the former editions, the comprehensive scope and depth of scholarship characterizing this work. Every phase of hygiene, with a few exceptions, is discussed in its numerous bearings. These exceptions cannot be dismissed without comment. It is difficult to understand why no mention is made of the rôle of bacteria carriers in the transmission of disease, a subject whose importance has challenged attention during the past few years; it is equally difficult to explain the omission of adequate reference to the modern conceptions of contact infection as contradistinguished from aerial infection. These subjects are vitally connected with public sanitary administration and deserve a complete discussion in a treatise on practical hygiene.

A Working Manual of High Frequency Currents. By Noble M. Eberhart, A.M., M.S., M.D., Professor and Head of the Department of Electrotherapy, Chicago College of Medicine and Surgery; Professor of Radiotherapy, High Frequency, and Vibration, Illinois School of Electrotherapeutics; Radiotherapist, Francis Willard Hospital; formerly Attending Physician Cook County Hospital; formerly Professor of Electrophysics, Post-Graduate Medical School, Chicago; Member Chicago and Illinois State Medical Societies, American Medical Association, American Medical Editors' Association, Press Club of Chicago, Victoria Institute or Philosophical Society of Great Britain, etc.; Fellow, American Academy of Medicine; Fellow, American Electrotherapeutic Association; author of "Practical *X*-Ray Therapy," "Brief Guide to Vibratory Technique," etc; Associate Editor, American Journal of Physiologic Therapeutics; Electrotherapeutic Editor Therapeutic Medicine and the Medical Brief. Price $2.00. Chicago: New Medicine Publishing Co., 1911.

The physician who is considering entering the field of electrotherapeutics is often bewildered by the apparent mass of technical knowledge required and is frequently at a loss to know where to look for enlightenment. Dr. Eberhart, in this book, has inserted only enough of the technical to give the physician sufficient knowledge to operate the common forms of apparatus on the market and intelligently apply the high frequency currents in the treatment of disease. A chapter is devoted to the practical technique required in treating the specialties and another to practical high frequency therapy. Ozone, its nature, physiological action, methods of administration, and therapeutic indications, are briefly considered. The book should certainly prove of value to the physician contemplating using the high frequency current, as it has simplified, to a large extent, a very difficult subject.

The Treatment of Fractures. With Notes Upon a Few Common Dislocations. By Charles Locke Scudder, M.D., Surgeon to the Massachusetts General Hospital, Lecturer on Surgery in the Harvard Medical School, Fellow of the American Surgical Association, Member of the American Urological Association. Seventh Edition, Thoroughly Revised and Enlarged. With 990 illustrations. Price $6.00. Philadelphia and London: W. B. Saunders Company, 1911.

The excellent features of this work have been commented upon so many times that the task of the reviewer would be simply one of reiteration. In the presentation of the simplest details necessary in the treatment of fractures, in the elucidation of the principles governing this treatment, in the host of photographic illustrations representing every important phase of the subject, this volume is preeminently one adapted for the general practitioner and student. The present edition contains, besides a new chapter on the operative treatment of fractures, new material, particularly in connection with the following subjects: fractures of the skull; old fractures of the nasal bones; fractures of the spine; excision of the shoulder joint; damage to the musculospinal nerve; fractures of the neck of the femur; old fractures of the lower end of the tibia; and injuries to the lower tibial epiphysis. In paper, typography, illustration, and binding this volume combines the best of the publisher's art.

Praktische Ergebnisse auf dem Gebiete der Haut und Geschleshtskpankheiten. Erste Jahrgang. Herausgegeben. Von A. Jesionek, Giessen. Wiesbaden: Verlag von J. F. Bergmann, 1910.

During the last few years collections of monographs dealing with the recent advances in various medical branches have become very popular in Germany. The volume before us represents such a collection of articles on cutaneous and genitourinary diseases. The ten subjects treated are: Gonorrhea, Radium and *x*-rays in therapeutics, Arsenic in therapeutics, General therapy of cutaneous diseases, Toxic exanthems, Relation of cutaneous to organic diseases, Wassermann reaction, Campaign against venereal diseases, Leucemic affections of the skin, and, finally, Eczema. These articles contain very extensive bibliographies, with short extracts of the newest publications on the subject treated; they thus save much time for the busy practitioner while acquainting him with progressive development of knowledge in the special subject. We have nothing but praise for this publication, as for other similar ones in the domain of internal medicine, pediatrics, surgery, etc. American skin and genitourinary specialists would do well to acquaint themselves with this volume and any of the series that may follow.

International Clinics. A Quarterly of Illustrated Clinical Lectures and Especially Prepared Original Articles, etc. By leading members of the medical profession throughout the world. Edited by Henry W. Cattel, A.M., M.D., Philadelphia, U. S. A. Volume II, Twenty-first Series, 1911. Philadelphia and London: J. B. Lippincott Company, 1911.

The present number of this well-known periodical consists of over twenty-five articles from the domain of medicine, surgery, obstetrics and gynecology, neurology, laryngology, ophthalmology, and pathology. We can name but a few articles in this review: Edward Turton writes on constipation, paying special attention to causes and treatment; Fenton B. Turck writes on the diseases produced by the *Bacillus coli communis* in the intestines, allotting a much more important rôle to this organism in the etiology of disease than is currently accepted; Friedenwald and Leitz publish a study of the action of various intestinal antiseptics upon gastric digestion; Cumston considers the surgical aspects of typhoid fever; Thomas communicates his experience with intravenous use of salvarsan, depicting one more form of apparatus for the purpose; Smith reviews the advances in obstetrics in the last twenty years; Robertson writes on the neoplasms of the larynx, etc., etc. These few titles show the variety of subjects treated. The readers need hardly be told what a valuable library of ready reference is gradually formed by the acquisition of the successive volumes of this quarterly.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held October 19, 1911.

Dr. L. Emmett Holt, Vice-President, in the Chair.

Resolution Concerning the Library.—The proposition to amend By-Law 13, Section 15, by substituting the following was unanimously carried. "The Library shall be open on week days to the Fellows, and Associate Fellows, and to persons specified in Sections 7 to 11, inclusive, of this Chapter, from 9 A.M. to 10.30 P.M., and to the Public from 9 A.M. to 2 P.M., excepting during June, July and August, when the Library shall be closed at 12 M. Saturdays, and at 6 P.M. on the other week days, and, also, excepting such time during the year, as it may be necessary to close the Library for cleaning and repairs. The Library may also be open on Sundays and legal holidays, to the members of the Academy, from 10 A.M. to 5 P.M., as may be deemed desirable by the Committee on Library, and approved by the Council."

The Rôle of Salts in the Preservation of Life.—Dr. Jacques Loeb of the Rockefeller Institute delivered this, the Wesley M. Carpenter, lecture. He said that less was known of the rôle of the salts in the animal body than of the rôle of the three other main foodstuffs, namely, carbohydrates, fats, and proteins. As far as the latter were concerned they knew at least that through oxidation they were capable of furnishing heat and other forms of energy. The neutral salts, however, were not oxidizable. Yet it seemed to be a fact that no animal could live on an ash-free diet for any length of time, although no one could say why this should be so. They had a point of attack for the investigation of the rôle of the salts in the fact that the cells of their bodies lived longest in a liquid which contained the three salts, NaCl, KCl, and $CaCl_2$ in a definite proportion, namely, 100 molecules NaCl, 2.2 molecules KCl and 1.5 molecules $CaCl_2$. This proportion was identical with the proportion in which these salts were contained in sea-water; but the concentration of the three salts was not the same in both cases. It was about three times as high in the sea-water as in the blood serum. A series of experiments were made which seemed to give an answer to the question why it was that the three salts played so important a rôle in the maintenance of life. In order to make it easier for those present to follow the enumeration of these experiments he stated briefly the chief conclusion. They knew that every cell represented a chemical factory in which specific chemical reactions took place and that these reactions were different from those going on in the cells of other tissues and in the blood. If a cell was to do its work properly, it had to be shut off to some extent from the blood. This privacy was guaranteed to each cell through the condition of the surface layer of its protoplasm. It seemed that nature had invented a process of "tanning" through the three salts NaCl, KCl, and $CaCl_2$ whereby the surface layer of each cell was rendered comparatively impermeable. In this "tanning" action of the three salts he was inclined to see the explanation of their life preserving action. In order to picture the extent to which the life of many animals depended upon the co-operation of the three salts he mentioned experiments made on a small marine crustacean, Gammarus, of the Bay of San Francisco, which led to the conclusion, that in order to preserve the life of the crustacean Gammarus, the solution must not only have a definite concentration or osmotic pressure but that this osmotic pressure must be furnished by definite salts, namely, NaCl, KCl, and $CaCl_2$ in the proportion in which these three salts existed in sea-water (and in the blood); this could be demonstrated for other marine animals. What was the rôle of these salts in these cases? The botanists had always considered salt solutions as nutritive solutions, but the experiments Dr. Loeb had made on a small marine fish, Fundulus, proved beyond question that this was not the case. He proved that a mixture of NaCl-$CaCl_2$ did not act as a nutritive solution but as a protective solution. KCl and $CaCl_2$ were only necessary to prevent the harmful effects which NaCl produced if it was alone in solution and if its concentration was too high. They were dealing, in other words, with a case of antagonistic salt action, an antagonism between NaCl on the one hand and KCl and $NaCl_2$ on the other. The question now arose: what was the mechanism of antagonistic salt action? The answer to this question lay in observations on the eggs of Fundulus. Fish, so long as it was in the egg, was separated from the surrounding solution by the egg membrane which possessed a small opening, the so-called micropyle, through which the spermatozoon entered into the egg. With a process of hardening or "tanning," it became more impermeable for the NaCl solution. This process of hardening was brought about apparently very rapidly if they added to this solution a trace of a salt of a bivalent metal like Ca, Sr, Ba, Zn, Pb, Mn, Ko, Ni, etc. Not only were the bivalent metals able to render the NaCl solution harmless but the reverse was also the case, namely, that NaCl was required to render the solutions of many of the bivalent metals, for instance, $ZnSO_4$, harmless. They arrived at a new conception of the mutual antagonism of two salts, namely, that this antagonism depended upon a common co-operative action of both salts on the egg membrane, by which this action became completely or comparatively impermeable for *both* salts. And from this fact they drew the further conclusion that the toxicity of each of these salts, if it was alone in the solution, was due to the fact that it could pass through the membrane rather rapidly and reach the embryo. As long as they assumed that lack of the two antagonistic salts acted, if applied singly, in the opposite way from its antagonist it was impossible to understand these experiments or find an analogue for them in colloid chemistry. But if they realized that NaCl alone was toxic because it was not able to render the egg membrane impermeable and that $ZnSO_4$ if alone was toxic for the same reason, both combined were harmless since for the "tanning" of the membrane the action of two salts was required, these experiments became at once clear and appeared in harmony with other experiences in the physicochemical analysis of the phenomenon of "tanning." It was shown that the antagonism between KCl and NaCl did not differ in principle from that of the antagonism between NaCl and $ZnSO_4$ for the egg of the fish. It was only due to the high concentration of the NaCl in the sea-water that, in addition to KCl and NaCl, $CaCl_2$ was needed. Cases were reported which proved that the life preserving effect of the combination of NaCl-KCl-$CaCl_2$ in definite proportions was not due to the fact that the organisms were adapted to this mixture but to a specific protective effect of the combination of the three salts upon the cells. Observations on the sea-urchin suggested the possibility that the combination of the three salts in their definite proportions and concentration had the function of forming a surface film of a definite structure of texture around the protoplasm of each cell by which the protoplasm was kept together, protected against, and separated from the surrounding media. *Conclusions.*—From all experiments they drew the conclusion that the rôle of NaCl, KCl and $CaCl_2$ in preserving the life of the cell was primarily due to a structural, a kind of tanning, effect which they exercised upon the surface film of the protoplasm of the cell. Through this action the film held not only the protoplasm of each cell together, but also required the qualities of semi-permeability necessary for the maintenance of the individual life of the cell. Various facts indicated that in this effect the

action of the Ca was perhaps the most important. This action of the salts was in some cases, if not universally, due to an action upon the proteins. This structural effect of the salts was not entirely irreversible. If they put cells into abnormal salt solutions the surface film might undergo modifications and salts might interact with the protoplasm which were formerly excluded from such interaction. The fact that, for example, the muscle twitched in the pure NaCl solution and was prevented from twitching through the addition of $CaCl_2$ might be due to the fact that in a pure NaCl solution the NaCl might enter through the sarcolemma while when Ca was present the diffusion of the NaCl into the muscle was retarded or entirely inhibited. If instead of NaCl a pure solution of Na oxalate was used, the removal of the Ca originally present in the surface layer facilitated the entrance of Na oxalate and the twitching occurred more rapidly than if they applied NaCl. The author did not believe that this exhausted the rôle of the salts in the body, but they understood now at least why it was that although the salts could not furnish energy, no organism could exist for any length of time on an ash-free diet. The salts, especially NaCl, KCl, and $CaCl_2$, were needed for the formation of the physical or structural qualities of the organisms, especially of the surface films of the protoplasm of the cells, without which life was impossible.

SECTION ON SURGERY.

Stated Meeting. Held October 6, 1911.

DR. JOHN A. HARTWELL, CHAIRMAN PRO TEM.

Gangrenous Appendicitis with Perforation and General Peritonitis.—Dr. SETH M. MILLIKEN presented a motorman, twenty-six years old, whose family and previous histories were negative. September 15 at about 8 P. M. he was seized with violent cramp-like abdominal pain. He had nausea and vomiting. He ran his car, however, until 2 A. M., working off and on during this day. Sunday morning, two days after the onset of his symptoms, he reported for service. He vomited several times and was not allowed to take out a car. Between 4 P. M. and 8 P. M. he called on a friend, carrying his baby several blocks. Sunday night he was very ill. Early Monday morning he went to a doctor. The examination made was very painful. He walked home. Late that afternoon the doctor called and, seeing his condition was worse, sent him to the hospital, where he was admitted at 8 P. M. September 18. He then had a temperature of 102.6° F., pulse 108, and respirations 24. There was great abdominal tenderness. The leucocytes numbered 12,000 and the polymorphonuclears were 82 per cent. The vomited matter was without odor. Dr. Milliken saw him at 9 P. M. The patient had a very anxious expression. The abdomen was rigid, was tympanitic in the middle and flat over both flanks. There was tenderness all over the abdomen. Operation was performed at 9.30 P. M. As soon as the abdomen was opened there came out gas, feces and yellow pus. A loop of intestine interfered much with the operation. The appendix could be felt low down in the pelvis, lying across the hollow of the sacrum, without adhesions. Pus was pouring into the abdominal cavity. The appendix was drawn up, ligated, cut off, the stump cauterized and inverted. Irrigation by the Blake method was employed and pus seemed to come from everywhere in the abdominal cavity. Twelve gallons of saline solution were used before the fluid came away clear. His condition was so serious that the doctor thought he would surely die. Strychnine and digitalis were given and the irrigation by the Murphy method started. The next morning the patient was very much better and asked for something to eat. He made an uneventful recovery.

Dr. ROBERT T. MORRIS said that it was very important that they should learn the character of the bacteria in the pus. Many overlooked a fact brought out by Welch that at the beginning of any infection of the peritoneum the staphylococcus albus spread over the peritoneum very rapidly, and a great deal of this pus rapidly became sterile. One might, however, have a terminal infection following this which was virulent in character. In a large series of cases of general suppurative peritonitis, with apparently the entire peritoneum involved, in many the pus would be found to be sterile. These patients made astonishing recoveries.

Partial Gastrectomy for Carcinoma.—Dr. JOHN DOUGLAS presented a man, forty-five years old. His family history was negative. He was moderately alcoholic. The history of his previous illness dated back one and a half years, when his condition was practically what it was when he came under observation. He vomited frequently, and had severe pain particularly after meals; this pain was relieved by vomiting. His present illness began two weeks before he entered the hospital on July 12. He had lost his appetite, and had sharp lancinating pain in his stomach. Partaking of a heavy meal produced the greatest pain. He vomited every day and during the last two weeks vomitus was dark and coffee-ground in character. He lost 10 pounds in three weeks, weighing on admission 120 pounds. There was an absence of free hydrochloric acid in the gastric contents. The *x*-ray pictures aided them in making a diagnosis of carcinoma of the stomach. On July 24 operation was performed. The carcinoma was found occupying about 3 x 2½ c.m. of the lesser curvature of the stomach to the left of the pylorus. A little over one-half of the stomach was removed and a posterior gastroenterostomy done. On the seventeenth day after the operation the photographs taken showed plainly the bismuth passing through the wound. The patient was discharged on the twenty-first day. In the five weeks following the operation he gained 16 pounds in weight. He now weighed 145 pounds. The interesting points in this case were the *x*-ray photographs showing the situation of the carcinoma, the presence of a tumor not palpable, and no dilatation of the stomach on account of lack of involvement of the pylorus.

Partial Gastrectomy for Carcinoma.—Dr. JOHN DOUGLAS presented a man, fifty-three years old, who was admitted to Bellevue Hospital August 3, being referred there by Dr. Satterlee. His previous history was negative. About eight months before his admission he complained of gastric pains which were relieved by belching up of gas. He had no appetite. He was never nauseated and never vomited. The belching of gas was very frequent. About one month ago he became jaundiced, and found that he had lost between 30 and 40 pounds in weight in eight months. There was no free hydrochloric acid in the gastric contents. He had had no vomiting at all. An *x*-ray was taken by Dr. Ewald. A carcinoma was found to involve fully two-thirds of the lesser curvature of the stomach. At operation between two-thirds and three-fourths of the stomach were removed, just enough of this organ being left to enable them to do a posterior gastroenterostomy. Just what the outcome would be was questionable. He was able to eat. He had gained 9 pounds in weight since the operation. He never vomited before or after operation. Both these cases showed the utility of the *x*-ray in making a diagnosis of these cases of carcinoma of the stomach.

Dr. ROBERT T. MORRIS said that it was not only for purposes of diagnosis in cases of suspected carcinoma that a fluoroscopic examination was made, but to determine the motility of the stomach which might give a clew to some interference with stomach function.

Resection of Small Intestine for Sarcoma.—Dr. JOHN DOUGLAS presented a patient, twenty years old. There was

no history of malignant disease in the family. His habits were regular, and he was not alcoholic. He denied venereal diseases. He was admitted to the hospital July 1. Six weeks prior he noticed a tumor in his abdomen and he felt uncomfortable when he was up and about. He had to stop work because of this discomfort and weakness. He had no constipation nor abdominal symptoms. Examination revealed a mass about one-half again as a fist, lying to the left of the median line and between the umbilicus and symphysis. It was irregular in outline and moderately hard. It was first thought to be fecal impaction; then it was believed to be a cyst; in fact the diagnosis was not made until the abdomen was opened. An exploratory incision was made and this mass was found between the umbilicus and the symphysis and involving the small interstines. It was grayish-white in color and adherent to the bladder and omentum. A diagnosis of sarcoma of the small intestine was made. At operation between 5 and 6 c.m. of the small intestine on each side of the growth were removed. The bowels moved the day after operation without the use of any cathartic. The growth removed was a lympho-sarcoma. Very few of these cases had been reported in the literature.

Dr. Edward W. Peterson reported the case of a patient, twenty-eight years old, with sarcoma of the rectum. He only saw him last week. Sections of the growth were taken and the diagnosis made. Resection of the rectum was proposed but declined. The patient went to another hospital where the growth was completely removed.

Dr. Robert T. Morris recalled a case of sarcoma of the large intestine that fell under his care. It involved the splenic flexure. The patient was referred to Dr. Judd, who kept him alive three years. It was a spindle cell-sarcoma.

Tumor of the Tibia.—Dr. John Carl Arpad Gerster presented a boy, ten years old. There was no history of any specific disease. The first unusual thing noticed was that the right leg seemed larger than the left; he seemed to walk on the toes of his left foot. He had no pain, no fever, and practically nothing abnormal except that this one leg appeared to be swollen and longer than the other. The *x*-ray photograph was interesting. The tibia and fibula on the right side were one and a quarter inches longer than on the left side. The swelling appeared to be about one and a half inches above the ankle. In this case the question of diagnosis arose. A number of *x*-ray plates were shown. In comparing the two fibulae there appeared what looked like a diffuse periosteal thickening on the right side; when the two tibiae were compared a distinct tumor on the inner side of the tibia could plainly be made out. Was this tumor of specific nature? Was it a proliferative process in the leg in a child with primary or secondary lesions not apparent? On the other hand it might be a sarcoma of the tibia. If so it would be subperiosteal. Just why one leg should be longer than the other was hard to answer. This might be a congenital anomaly. The Wassermann and Noguchi tests had been made. There seemed to be some asymmetry of the face. The subsequent course of the case would be reported at some future meeting of the Section.

Dr. Robert T. Morris thought that the question of diagnosis in this case would resolve itself into the question of subperiosteal sarcoma. With regard to the lengthening, it was supposed to occur from the epiphysis rather than from the diaphysis; in this instance the epiphysis was not involved. He remembered one case of pseudo-sarcoma in which the hyperplasia involved the entire leg and there was lengthening, but in this instance the medullary structures were involved.

Postoperative Treatment of General Suppurative Peritonitis.—Dr. Aspinwall Judd read this paper. He stated that various methods of treatment of this condition at the time of operation had been exploited which agreed in only one point of technique, namely, the necessity of the most rapid operation possible compatible with any sort of thoroughness. Dr. Judd expressed himself as of the opinion that the flushing of the peritoneal cavity with various solutions, the making of multiple incisions, except in rare instances, and the handling of the intestines were to be avoided wherever possible. Every effort should be made to avoid driving bacteria into the upper part of the abdomen where the lymphatic supply was particularly abundant and where the absorption of toxines was so rapid as to produce an overwhelming effect upon the system. The wiping off of peritoneal surfaces was also contraindicated. In the 38 cases whose histories the writer presented he had followed out the general method of fairly wide single incision, if by this incision he was able to reach the seat of the infection, evacuate the septic contents by gentle sponging, and effect the repair of the viscus as rapidly as possible. Where by a prolonged search for an appendix the life of the patient was endangered, Dr. Judd said he merely placed a large drain at the site of the lesion and returned the patient to bed as soon as possible. In many of his cases he had administered at the time of the operation or immediately afterward an infusion of from one thousand to fourteen hundred c.c. of normal saline solution, in which from one to two drachms of adrenalin solution had been added. In over 50 per cent. of his cases the cultures were either streptococcus or streptococcus plus colon bacillus. In the remainder the colon bacillus was predominant. Immediately upon being returned to bed the patient was placed in the exaggerated Fowler position. If the condition was desperate intravenous infusion was administered. This had proved very much more effectual than any other methods and was no more difficult to administer. As light a dressing as possible was applied, three or four layers of sterile gauze, and this was kept moist with saline solution and changed as often as required. An ice coil was applied and kept going continuously. Icebags did not answer the purpose; they were too weighty and failed to keep an even temperature. Murphy's drip, a continuous rectal irrigation, was started at once. In some instances the patient had absorbed as much as 140 ounces of normal saline in twenty-four hours by this method. A minority of patients were unable to retain the fluid but would absorb four ounces of saline to which one ounce of whiskey might be added every three hours. An enema of this size would often be taken up every three hours where one of eight ounces administered every four hours would be rejected. Absolutely nothing was given by the mouth. The lips and tongue might be moistened with water applied with a swab but not a drop was allowed to be swallowed. This treatment was persevered in from forty-eight hours in the milder cases to thirteen days in one of the cases reported. To prevent desiccation, a second, or even a third, intravenous infusion of one thousand c.c. of normal saline solution was administered. The writer had given three infusions within four days with no evil results. This treatment greatly reduced the craving for water. No opium or sedatives of any kind were given as they tended to diminish the excretions and secretions. Strychnine and other heart stimulants were given as required. This treatment absolutely inhibited peristalsis, pain was completely absent, and distension rarely occurred. Hunger was also completely abolished. Each twenty-four hours the drains were started, pulled out from one-half to one inch and cut off; this in conjunction with the moist, wet dressing insured good capillary action and copious drainage. If at the end of forty-eight hours the patient was doing well he reduced the Murphy irrigation to twelve hours in twenty-four, replaced the large drainage with short shock

blocks, or if Fowler's enemata were used omitted them during the night. A medicine dropper full of water was administered tentatively, alternating with a liquid food preparation, every fifteen minutes. This was done as much for the psychic effect as for the effect of the fluid itself. If after another twenty-four hours the patient continued to do well the ice coil was used each alternate twenty-four hours. The quantity of fluid given by the mouth was doubled or trebled, depending upon its failure to produce peristalsis. The bowels in all cases were moved by enemata alone up to the sixth day. In those cases in which the appendix was not found or the hole in the intestine not repaired, a fecal fistula usually made its appearance from the third to the sixth day. This was of no consequence as 90 per cent. of these fistulae closed of their own accord under appropriate treatment with permanganate of potash solution with a high irrigator containing two to four quarts and the insertion of a soft rubber tube to the bottom of the fistula, the tube being reduced in length and caliber as the fistula closed. Where in spite of all precautions a patient started up a sudden temperature, an intravenous infusion would almost invariably bring the temperature down to somewhere near normal within from six to twelve hours with a corresponding improvement of pulse. The aim of the writer's treatment in these cases had been to absolutely limit peristalsis, with a consequent absence of pain, to prevent the absorption of septic material, and to produce an exosmosis into the peritoneal cavity with a subsequent washing out of this septic material. With the use of the ice coil the writer had never seen paralysis of the vasomotors with a consequent dilatation of the blood vessels. Where it had been necessary to deprive the patient of food for more than four days in a well nourished individual, or more than forty-eight hours in a fragile person, nutrient enemata had been alternated with the Fowler's enemata. If this was done it was essential to wash out the rectum thoroughly once a day. Where the stomach was distended it was customary to wash it out as often as might be required. In two or three cases where postoperative ileus had developed he had administered as a last resort three or four minims of oleum tiglii suspended in one ounce of castor oil through a stomach tube. In one such case the procedure was repeated three times within thirty-six hours. This measure was resorted to only in cases in which death was inevitable without some radical procedure, and after this measure had proved successful, the routine treatment was immediately resumed. Dr. Judd had used autogenous vaccines to some extent but was not prepared as yet to report his results.

Dr. Edward W. Peterson asked how one could determine that there was a general suppurative peritonitis present through such small incisions.

Dr. Clarence A. McWilliams said that the question, whether to flush out the abdominal cavity in these cases or not, was a very interesting one; the general trend among surgeons today was not to wash out this cavity; such a procedure seemed to increase the shock; washing the abdominal cavity, even if thoroughly done, diluted the poison to such an extent that it was more easily absorbed and the patients died quicker. However, if the peritoneal cavity could be thoroughly and quickly washed out, it seemed to him that this would be an advantageous thing to do. The method used at the Presbyterian Hospital consisted of a suction apparatus; the salt solution was introduced by the ordinary irrigating tubes; then the suction tube was placed at various parts of the abdomen and the fluid withdrawn.

Dr. William Henry Luckett noticed that Dr. Judd gave enormous doses of stimulants. He had found that these patients with general suppurative peritonitis and suffering from shock, if placed in the exaggerated Fowler's position, required stimulation to keep them alive. There was the choice of free stimulation or letting the bed down a little bit. In cases of general peritonitis following pregnancy the late Dr. Pryor believed that the best thing to do was to perform a posterior vaginal celiotomy, and packing around the broad ligament with iodoform gauze, keeping the packing in until iodine appeared in the urine. Dr. Luckett said he did not see these cases of general peritonitis; he did not recall a single case in an active service. Of course they often saw cases of pus in the peritoneal cavity. He thought there must be something else to enable them to make a diagnosis of general suppurative peritonitis besides what was found by looking through a five-inch incision in the abdominal wall.

Dr. John A. Hartwell said that the subject under discussion was one that was always very prolific. He remembered such a discussion before the Surgical Society; the question was, should they use irrigation at the time of operation. Cases were shown on whom irrigation had been employed by the Blake method. This was a siphonage produced by a special device. At that time the method was severely criticised. The majority of those present were of the opinion that irrigating the abdominal cavity was not a good procedure. There was only one gentleman present besides himself that believed it to be a good procedure and he later found that he was the only one present who had a Blake tube. Their contention was that the use of the tube tended to do harm. At a subsequent meeting there was introduced a tube which was somewhat similar in construction to a vacuum cleaner and the gentleman who was especially bitter at the former meeting, and who had been very strong in his condemnation of these tubes, said that this tube was one of the best things to use because there was pus in the abdomen and the presence of pus there was dangerous. So far as his experience went he had not used the Blake tube; there was no way of getting rid of the pus that he considered to be safe. He therefore let it alone. Nature could take care of a great deal of the exudate.

Dr. Aspinwall Judd said that blood cultures were taken in practically every case. There was no great diminution in the body fluids; the patients did not become desiccated at all. They were never thirsty and did not have a dry tongue. They claimed they never felt the ice coil. He did not wish to be understood as saying that he used only small incisions; he made incisions sufficiently large to meet the requirements. If necessary an increase in the body fluids might be brought about by means of enemata and intravenous infusions. Pharmacists stated that they got no systemic effects from the use of adrenalin; but clinicians did get the results; they got distinct rises of blood pressure from the use of adrenalin but the dose must be larger than the pharmacists advised. In determining whether there was present a diffuse suppurative peritonitis or not, it seemed to him that the character of the pus would determine that point. If the blood culture showed the presence of streptococci together with the colon bacilli it meant, in all probability, that there was present a general diffuse peritonitis.

MEDICAL SOCIETY OF THE STATE OF PENNSYLVANIA.

Sixty-first Annual Meeting, at Harrisburg, September 25 to 28, 1911.

(Continued from page 896.)

SECTION ON MEDICINE.

Tuesday, September 26—First Day.

Dr. Edgar M. Green of Easton in the Chair.

Chairman's Address.—Dr. Edgar M. Green of Easton said he would not for one moment discourage the most scientific and painstaking labor to make an accurate diagnosis, but what advantage was it to us in our practice and

of what benefit were we to our fellow men if we spent all our time and used all our knowledge merely in diagnosis? It mattered little to the patient whether he had one-half or two-thirds of the lower lobe of his left lung involved. It sufficed for him to know that he had pneumonia. Much more important to him was that his treatment should be so carried on that relief was given and a return to health secured. Great advances had been made in the treatment along the line of serum therapy, but this had reached comparatively few diseases and the treatment of most of our patients must still be limited to the assistance of nature in her work.

Surgical Treatment of Poliomyelitis.—Dr. G. G. Davis of Philadelphia said that as long as there was any ground for hope of improvement in poliomyelitis no radical measures such as operation should be undertaken. This usually applied to the first year of the disease. During this time apparatus was used to support the part and to substitute as far as possible the paralyzed muscle. If the knee was weak stability could be obtained by a brace. If the toe dropped it might be held up by a rubber band. When the body weight was placed on a paralyzed limb it tended to become distorted: braces prevented this. Exercise was the most important agent. It consisted in encouraging the patient in the attempt to use the paralyzed parts. Finally after two, three, or more years, when improvement apparently ceased, various operative procedures could be resorted to.

Pennsylvania's Work on Poliomyelitis.—Dr. S. G. Dixon, Commissioner of Health of Pennsylvania, stated that in January, 1910, the Advisory Board of the Pennsylvania Health Department adopted a resolution causing poliomyelitis to be classed as reportable. Since July, 1910, 1,076 cases had been reported. The geographical distribution was general. Geological studies seemed to indicate a relationship between the disease and wet subsoil, but neither vegetable nor insect life could be determined to be positively related to the spread, although simultaneously with the outbreak there was an unusual prevalence of mosquitos. Out of the 1,076 cases 739 occurred in children under 5 years of age. The most important work performed in the State Laboratory was the discovery and description in detail of a hitherto unobserved organism in the blood of children and monkeys suffering from the disease.

Dr. C. K. Mills of Philadelphia said he had had a large experience with poliomyelitis, but could not say much about the nature of the disease except to express his conviction that it was carried by some form of insect and that the microorganism to which it was due was very likely of animal rather than of vegetable nature. He had seen quite a number of cases in which the disease was characterized by pain due to various causes, among them coincident meningitis or multiple neuritis, also to constrained positions due to relaxation of the muscle incident to the paralysis. The differential diagnosis was easy as there was scarcely any other condition that could be confounded with it. He thought a great mistake was made in treating those patients too much and too soon. Nothing was so dangerous perhaps as the too early and too severe use of electricity. After a time electricity could be used and should be used with more care, but only under the observation of a physician who understood it.

Dr. Tom A. Williams of Washington, D. C., said that in 1910 there had been 500 cases within two months in Washington, D. C. No new early symptoms were discovered which would enable them to predicate that a case was one of poliomyelitis. It seemed wise that in times when the disease was suspected all febrile cases should be isolated for some days at least.

Technique and Clinical Significance of the Wassermann Reaction.—Dr. John L. Laird of Philadelphia presented a statistical report based on 2,672 reactions on 1,555 cases. Among 808 reactions in non-syphilitic cases with lesions 767 were positive, 37 negative, and 4 doubtful. In 458 reactions of syphilis without lesions 278 were positive, 174 negative, and 6 doubtful; in another series of syphilitic cases in which the stage of the disease and the amount of treatment were uncertain in 116 reactions 101 were positive, 12 negative, and 3 doubtful. In parasyphilitic conditions among 223 reactions 177 were positive, 45 negative, and 1 doubtful. In syphilis after treatment with salvarsan among 177 reactions 121 were positive, 43 negative, and 13 doubtful; in doubtful cases among 408 reactions 66 were positive, 294 negative, and 28 doubtful. In non-syphilitic cases among 482 reactions were all negative.

The Relation of Syphilis to Diseases of the Nervous System.—Drs. Theodore Diller and W. R. S. Denner presented this paper in which they said it was common to divide syphilitic affections of the nervous system into two groups, namely active syphilis and parasyphilis. In active syphilis the involvement of the nervous system was usually, if not always, secondary to the blood-vessels and meninges, whereas in parasyphilis the lesions were ably produced by the toxins of syphilis and were essentially incurable in character. Among the most important symptoms pointing to cerebral syphilis were persistent headache growing worse at night, vertigo, and mental torpor. When syphilis attacked the base of the brain various nerve palsies might be noted. When, in the presence of severe, persistent headache, there were apoplectiform convulsions and no optic neuritis it was to be suspected that the meninges of the convexity were chiefly involved. Whether all cases of tabes and paretic dementia were secondary to syphilis was still somewhat a debated question, but it appeared that the weight of evidence was leading more and more to an affirmative answer to this question. Brain syphilis was to be distinguished especially from tumor. In doubtful cases one had come to let the laboratory findings settle the case.

Treatment of Syphilis.—Dr. Walter F. Donaldson of Pittsburgh presented this paper, saying that it was the family physician who had the best opportunity to treat syphilis. He most often saw it in its earliest manifestations when it was most easy to overwhelm the infection by diligent treatment and to instil into the mind of the patient just what syphilis was and what its treatment should be. The recognition of the spirochetes in the secretions of the primary lesion made reprehensible the practice of waiting for secondary manifestations before instituting treatment. The Wassermann and the Noguchi reaction were able to clear up the diagnosis in doubtful cases and to facilitate prompt application of proper therapy. The practitioner must not only be familiar with the disease but must also be prepared to put in practice the most scientific modes of treating it. Plans should be outlined for the patient from the first by which one might expect to see the patient often enough to keep control and long enough to cure. It could not be said that mercury given in proper form and appropriate does had not proved highly satisfactory in the treatment of syphilis. The use of arsenic in the treatment of syphilis had been overlooked until very recently. To-day it had reassumed its position second to mercury and iodine. Where potassium iodide was indicated he believed it was nearly always better administered with mercury, the best results being obtained by increasing doses. The use of salvarsan in properly chosen cases was undoubtedly an improvement over other methods of treatment, but until many more years of experience with it had developed it must remain as an auxiliary to the tried and proven power of mercury.

Dr. Hillary M. Christian of Philadelphia said that in regard to the Wassermann test he was convinced as to its value. However, he would not pronounce an apparently healthy man necessarily syphilitic because

he responded to this laboratory test, neither would he say a man who had certain lesions was not syphilitic if he did not respond to the Wassermann test. In most of his work the Wassermann test was not needed. He thought it of the greatest value in nervous syphilis. Last May he reported a series of 70 cases that had been treated with salvarsan. He was then accused of being rather pessimistic, but he had tried it out since and had no reason to change his opinion.

Dr. Judson Daland of Philadelphia said the Wassermann reaction was unquestionably of the utmost importance in very many syphilitic conditions, not only from the standpoint of diagnosis, but also in judgment of treatment. Although there were certain conditions where it was to be preferred it seemed to him Dr. Donaldson had pointed out very clearly the point that one had in salvarsan an additional remedy capable of attacking syphilis in a different manner.

Wednesday, September 27—Second Day.

The Relation of the Streptococcus to Scarlet Fever with Active Immunization by Means of Streptococcic Bacterins.—Dr. John A. Kolmer of Philadelphia said that among the various organisms considered as the probable cause of scarlet fever streptococci had received the most study and attention, although they were regarded as secondary invaders and responsible for a high proportion of the complications. If streptococcic bacterin prevented scarlet fever, then streptococci bore a much closer relation to that disease than one was willing to admit. An inoculation, however, with the heat-killed streptococcic bacteria did not prevent scarlet fever. As scarlet fever was probably not due to the streptococcus, that organism being responsible only for the complications, the streptococcus bacterin might prevent a severe attack of scarlet fever by producing an immunity against secondary streptococcus infections.

Heart Stimulation in the Treatment of Lobar Pneumonia.—Dr. J. Irving Roe of Wilkes-Barre presented this paper and stated that pneumonia was one of the most fatal of all acute diseases. Therefore, its treatment was very important. The great danger with this disease lay in certain cardiovascular conditions, thus the heart rather than the lungs needed careful watching. Pericarditis, endocarditis, and myocarditis were common complications. As regards heart stimulation the wise physician withheld it until the heart begun to flag, a condition indicated by progressive rapidity, more feeble apex beat, and weak first sound. The condition was one of vasomotor paralysis with lowered blood-pressure and lessened systolic output. Strychnine had its value, not perhaps as a heart stimulant, but as a stimulant to the respiratory centers. The author stated that he had used camphor with most gratifying results. In approaching collapse adrenalin given in 1 c.c. doses of 1/1000 solution by hypodermoclysis, or venous transfusion, repeated every two to four hours, was the most likely to give relief.

Anaphylaxis in Its Relation to Bacterial Infection.—Dr. A. Barr Snively of Blue Ridge Summit read this paper. He said that anaphylaxis was a phenomenon with which all general practitioners should be familiar. Prophylactic doses of sera should not be given indiscriminately on account of the danger of sensitizing the patient against future injections which might become necessary. A careful history should be elicited concerning any hereditary or acquired asthmatic tendency or idiosyncrasy toward horses and stables. According to Anderson, old sera were just as potent as fresh sera, unit for unit, and less apt to give serum reactions. Antitoxin was in itself harmless. The period of incubation of certain diseases was analogous to the sensitization time of anaphylaxis.

Typhoid Fever with Relapse and Multiple Complications.—Dr. A. A. Eshner of Philadelphia reported a case of typhoid fever in a woman 30 years old, in which early in the course of the disease the urine contained albumin and tube casts, and in the third week there was hemorrhage from the bowel, in the fourth week bilateral parotitis, in the eleventh week hyperpyrexia to the extent of 106.6°. In the twelfth week a pure growth of typhoid bacilli was cultivated from the blood. The patient recovered after an illness of 13 weeks.

The Treatment of Cardiac Arrhythmia.—Dr. George W. Norris of Philadelphia said that the forms of cardiac arrhythmia were: (1) Sinus arrhythmia in which the normal inspiratory pulse acceleration and expiratory retardation become exaggerated. This might be symptomatically abated by atropine, but direct treatment was rarely necessary. Rest, diet, hydrotherapy, and massage constituted the chief line of defence. (2) Extrasystolic arrhythmia in which one or more beats were dropped, which usually resulted from accentuated myocardial excitability, although it might be due to heart block or diminished excitability. When temporary it neded no treatment; when persistent treatment consisted in lessening the work required of the heart muscle. (3) Auricular fibrillations. It was this variety which so often went hand in hand with the broken compensation of old rheumatic valvular lesions. These cases required rest, sleep, attention to diet, exercise, and excretions. When the compensation was bad, absolute rest with laxatives and restricted dry diet would often produce many beneficial results. It was in auricular fibrillation that digitalis accomplished its most brilliant results. (4) Heart block which was due to a depression of conductivity. For the serious form of heart block seen in myocardial disease no definite rule could be laid down. In incomplete block atropine in liberal doses often arrested the condition. Digitalis was contraindicated. If heart block was complete, digitalis might be beneficial. (5) Pulsus alterans, which was due to depression of contractility, a condition which could be inferred when we found an alternating pulse or a half frequency pulse. As this was an expression of exhausted or degenerated myocardium little could be expected by any direct treatment. The treatment might be said to be that of myocarditis in general.

Report of and Observations on a Case of Massive Pericardial Effusion.—Dr. Thomas W. Kay of Scranton read this paper. During the past winter five cases of pericardial effusion had come under his observation. In one case at least 4,000 c.c. of fluid were present. The gravity of the case depended not upon the quantity of fluid, but upon the intrapericardial pressure. Paracentesis pericardii was easily done and gave prompt relief, but was usually not permanent. By it one was never able to draw off all the fluid. Excellent results were claimed as a result of passing the trocar into the pericardium and introducing a rubber catheter through a rubber cannula well below and to the rear of the heart. Thoracotomy with incision and drainage of the pericardial sac had been reported to give good results.

Dr. A. Stengel of Philadelphia said that one feature of the discussion which appealed to all in everyday work was the matter of diagnosis as between the serious and the trivial form of irregularity of the heart. He thought that the treatment of cardiac irregularities was infinitely more unimportant than the diagnosis, because, after all, the trivial forms took care of themselves in the long run and the other forms were serious and would remain serious even in spite of treatment, though they might be helped. The matter of diagnosis was of importance mainly because a proper recognition of the forms that were unimportant had led to permission to the patient to follow a mode of life that in the end rid him of the trouble; or, on the contrary, if the physician looked upon it as serious and gave a serious prognosis, would lead to hopeless in-

validism. One ought to be very careful in making the prognosis in these cases. A good rule was that the more the patient was incommoded by subjective recognition of his cardiac irregularity the greater was the trivality of his condition. The use of digitalis was governed strictly by the effects and we should recognize that in actual cardiac disease it sometimes, even in proper doses, did harm. In very large pericardial effusions the fluid was mistaken for pleuritic fluid and the aspiration was made far out in the left side and a fluid was obtained, but it was really a pericardial effusion. As to the radical operation for pericardial effusion he said that it was desirable to have more evidence than the evidence that was quoted before we could unequivocally recommend this form of treatment for pericarditis. He would prefer to stick to the old paracentesis at present.

Symptomatology and Pathology of Tumor of the Pons—Pathological Report of One Case.—Dr. John H. W. Rhein of Philadelphia stated that the symptoms characteristic of tumor of the pons were crossed hemiplegia, that was, palsy of one or more cranial nerves, on one side, chiefly the 5th, 6th, 7th, or 8th nerve, and hemiplegia on the opposite side. The variability of the symptomatology, on the other hand, was also characteristic for obvious reasons when the tumor was an infiltrating glioma, which was the most frequent type of pontine tumor. The frequency of dysphagia and dysarthria should be emphasized. Paralysis of associated ocular movements was of extremely important diagnostic value as indicating the presence of a lesion of the pons.

Herpes Zoster.—Dr. Frank Crozer Knowles of Philadelphia read this paper. He stated that during the last nine years he had observed 21,337 case of skin diseases among which were 286 cases of herpes zoster. The disease was rare under one year of age, but three cases having been seen. The disease was seen in the negro race only twelve times. Ulceration, pustulation, abscess, and a hemorrhagic or gangrenous condition of the vesicles were noted in a few instances. Itching, pain, and burning persisted for some weeks after the attack in a few cases. Unusual locations noted were the hands, soles of the feet, scrotum, and penis. The mucous membranes were attacked in four cases. Trauma was apparently the cause in one case and arsenic in another. None of the cases was bilateral.

Officers.—The following officers were elected for the ensuing year: *Chairman,* Dr. Charles H. Miner, Wilkes-Barre; *Secretary,* Dr. James D. Heard, Pittsburgh.

(To be continued.)

AMERICAN ROENTGEN RAY SOCIETY.

Twelfth Annual Meeting, Held in Richmond, Va., September 20 to 23, 1911.

The President, Dr. Percy Brown of Boston, Mass., in the Chair.

(Concluded from page 848.)

The Röntgen Rays in Neurasthenia.—Dr. Arthur Holding of Albany, N. Y., believed that neurasthenia and other neuroses were often caused by conditions which did not have their origin in the nervous system, and which might be detected by the röntgen ray; therefore, it was advisable that all these patients be examined thoroughly by a competent röntgenologist. A few illustrative cases were the following: Case 1, obscure progressive paralysis of the arm, shown by the röntgen rays to be due to a supernumerary rib. Case 2, epileptiform convulsions, shown to be caused by unerupted teeth. Case 3, a very obscure gastrointestinal condition due to cardiospasm. Case 4, neurasthenia with obscure constant pain caused by hour-glass contraction of the stomach. The patient was regarded as a neurasthenic for twenty years. Case 5. autointoxication with nervous prostration, regarded as a case of neurasthenia due to visceroptosis. Case 6, neurasthenia proved to be a case of tuberculosis of the lungs. Case 7, neurasthenia cured by the removal of a stone from the kidney. Case 8, patient unable to walk because of pain in the feet and legs, thought to be due to a broken-down arch. The röntgen ray showed an arteriosclerosis in the arteries of the feet and determined the case to be one of intermittent claudication. Case 9, a painful condition of the wrist supposed to be a neuritis, shown, however, to be caused by tuberculosis of the bones. Case 10, severe case of neurosis which proved to be caused by a dislocation of the symphysis pubis.

Dental Defects as a Cause of Epilepsy.—Dr. Henry K. Pancoast of Philadelphia wished to call attention to the importance of including a careful examination of the teeth as a part of the general routine examination of all cases of idiopathic epilepsy. Dental defects might exist and be responsible for the epilepsy. In three cases examined by him such defects proved to be etiological factors because when they were remedied the patient was free from epileptic attacks. Such defects might exist without any clinical manifestation; in fact, that was the rule; therefore, it was advisable in all cases of epilepsy to include as a part of the routine examination of the head a careful examination of the teeth. This was especially important in the case of children, although cases had been discovered in adults where the epilepsy was caused by the dental condition. Any defects found must be remedied early in order to do any good, as they were usually, perhaps, only a contributing factor in the etiology of the condition. Moreover, in view of this fact there should be no relaxation in the vigorous application of any other therapeutic measures that had been practised, or which might be indicated.

Dr. E. H. Skinner of Kansas City, Mo., once heard a man speak against machine-made diagnoses, and yet diagnoses made by mechanical means were superior to mere gray matter diagnoses. The thermometer, microscope, röntgen ray and blood-pressure apparatus had superseded less accurate and exact aids in diagnosis. Many cases of gastrointestinal disturbances had been diagnosed as neurasthenia until the röntgen ray disclosed an ulcer of the stomach, which was substantiated by a careful inquiry into the history of the patient. The gastroenterologist claimed that gastroptosis was the cause of neurasthenia, while the neurologist held that neurasthenia was responsible for the gastroptosis. The röntgen ray would often disclose a condition which, if corrected, would dispel the neurasthenia.

Dr. George C. Johnston of Pittsburg said that, as for neurasthenia being caused by unerupted teeth, it was probably true that there was some connection between the irritation of impacted teeth or any other constant irritation and epilepsy—but only in the case of an individual who was going to have epilepsy anyway. For three or four years he had examined cases of impacted teeth removed by two extraction specialists, but he had yet to see a single instance of epilepsy from this cause. As for neurasthenia and neuralgia: he was asked to examine a gentleman who had been suffering intensely from tic douloureux for a long time. Careful examination with the röntgen ray finally disclosed a little area of caries just under the gum margin in which there was a tomato seed. When that was removed the neuralgia ceased, and it had not returned since. In another case the nervous disturbance was due to abscessed incisor teeth.

Dr. George E. Pfahler of Philadelphia was asked to examine a woman who had neuralgia in her right foot. The neurologist who referred the lady to him scouted the idea that the neuralgia might be caused by an abscessed tooth, although he had found two such teeth in the

röntgenogram. Two years later another physician referred the patient to a dentist, who treated these two teeth, and the neuralgia promptly disappeared.

Dr. Clarence E. Coon of Syracuse, N. Y., had seen a young man of seventeen who had begun to have attacks of epilepsy which increased in severity and frequency until his mind became affected. His family finally had to place him in an asylum for the insane. He became violent and unmanageable. He was asked to examine him and found four impacted wisdom teeth, which he advised to have extracted. This was done, and from that time on this man had not had a single attack of anything like epilepsy. Within two weeks after the operation he was rational and quiet. He gained rapidly in weight and was now entirely well. The speaker would not want to create the impression that he believed that epilepsy was solely caused by impacted teeth, or other dental conditions. In epilepsy, as in any other disease, perhaps more so, one must have the soil in which the seed could develop. It was particularly in those cases where the dental conditions did not give rise to clinical phenomena that one must include the mouth and teeth in the examination. But this was only one factor which might cause the epilepsy.

Compensating Displacements of the Thoracic Viscera in Pulmonary Tuberculosis.—Dr. Charles Lester Leonard of Philadelphia thought that compensation for the loss of expansion in the lungs took place through an increase in the capacity of their normal area, or through the interposition between the visceral and parietal pleura of an area filled with air, or fluid, or both. These changes must take place in proportion to the volume of the lungs involved in a pathological process. They were in a measure appreciable by the ordinary methods of physical diagnosis. The changes which could be noted by inspection and mensuration were, however, less marked in ratio with the extent of the disease than those within the thorax, which produced displacements or alterations in the position of the viscera. An internist connected with one of the largest institutions for the special study of tuberculosis did not believe that displacements of the viscera could occur so frequently in the earlier stages of the disease. He said that in some hundreds of post-mortems conducted at the institute they had failed to find such displacements. These pathological variations in the position of the thoracic viscera could be clearly shown only by the rapid röntgenograms that eliminated the heart's motion. Their exact position and interthoracic relations could only be fully appreciated by the rapid stereoröntgenogram. In the entire series of one hundred cases twenty-six displacements of the heart and aorta were found, with three cases of pneumothorax. In seventeen cases the heart was displaced to the right; in four to the left; and in five a rotation took place, with an upward displacement of the heart and aorta, so that the heart assumed an anteroposterior position. In two cases a superficial pneumothorax was found overlying the lower left lung, and in one case an acute hydropneumothorax of tuberculous origin was shown. A review of the cases in the entire series showed that those cases in which no displacement of the viscera was present were early lesions, in which no fibroid change had taken place, or that the lesions were not extensive and symmetrical, or that the heart was bound down by adhesions between the pericardium and the diaphragm. The unequal elevation of the two halves of the diaphragm, Williams' sign, was present in less than one-half of all the cases, and was not present where displacements of the interthoracic viscera had occurred. The pathological displacements of the thoracic viscera in pulmonary tuberculosis were the result of compensation for the destruction of expansive normal lung tissue by the disease. The displacing force was the result of one or two changes, or the combination of both, or, as in the case of acute pneumothorax, from the rupture of the lung. The consolidated lung area might undergo fibroid change and contraction, the contracting tissues drawing the heart and aorta with them, while the emphysematous lung on the opposite side assisted in their displacement. In addition to the displacements which caused compression of the diseased portion of the lung there were present in many cases an ossification of the costal cartilages and an approximation of the ribs over the affected area. The compensating displacements might be divided into four groups. Displacements of the lung by superficial pneumothoraces; displacements of the heart upward and into an anteroposterior position; displacements of the heart and aorta to the left; and displacements of the heart and aorta to the right.

The Control of Fracture Work by the Röntgen Ray.—Dr. Roland Hammond of Providence, R. I., said that the time was near at hand when no fracture or joint injury would be considered to have been properly treated if a röntgen examination had not been made. It was a well-recognized fact that a röntgen plate should be taken after an attempt at reduction had been made to see if the desired result had been obtained. Of almost equal importance was a plate beforehand to know accurately with what condition we had to deal—a fact not appreciated by the profession at large. With the knowledge thus obtained the reduction could often be easily made and with but slight trauma to the parts. Many cases now subjected to open operation and plating could be treated by extension and counter-extension after the method of Bardenheuer and Graessner, with as good anatomical and functional results, and at less risk and greater comfort to the patient. In many cases which seemed irreducible plates made while the patient was under ether and after successive attempts at reduction had been made would often give the clue to the situation, enabling the reduction to be made without resorting to an open operation. Some fractures were irreducible by the above methods and an open operation was necessary. In these cases an absorbable suture material should be used, if possible, reserving wire and plates for cases in which the fragments could be held by no other means.

Dr. Arthur Holding of Albany, N. Y., thought it was the röntgenologist's duty to impress on the surgeon that this fracture work must be controlled by the röntgen ray. Only by this means could we determine absolutely whether the approximation of the fragments was as it should be. We must not hesitate to advise the surgeon to sacrifice his pride and reset a bone. In fact the röntgenologist might be in the rather trying position of having to protect the surgeon and the patient. We must be careful, however, when we used the röntgen ray while the patient was still under the ether anesthesia. He had seen several instances where the spark had caused serious damage, even when the tube was not anywhere near the ether can or mask. The spark jumped to the iron bedstead and in that way got to the ether can, and in one case there was produced a conflagration in which the patient was injured seriously. The ether bottle should be out of the room and the can away from the patient's face before the tube was excited.

Dr. Lewis G. Cole of New York said that he used bromide paper instead of a plate. One could show as much on the paper as on the plate in from two to three minutes from the time the exposure was made. The prints might be made as rapidly as could be done. This applied not only to fractures, but to foreign bodies.

Dr. George C. Johnston of Pittsburg thought the only man competent to treat fractures correctly was he who controlled his work with the röntgen ray. It was also necessary to examine these fracture plates stereoscopically, especially in the case of fractures of the shoulder.

Röntgenographic Diagnosis of Ureteral Kinks Causing Intermittent Hydronephrosis.—Dr. G. M. Stover of Denver, Col., said that hydronephrosis had heretofore been recognized only in rather an advanced stage, when the dilatation of the renal pelvis was considerable. We had found, and had demonstrated by catheter tests, röntgenograms, and surgical operation that there was easily recognizable a much earlier stage of this condition, to be discovered before dilatation of the renal pelvis had taken place. A certain number of patients complained of pain in one or both kidneys; a pain somewhat like that of the classical hydronephrosis, but not relieved by the sudden passage of a quantity of urine and a disappearance of the tumor, and without the microscopic urinary findings of fully developed hydronephrosis; a pain suggestive, but not typical, of renal calculus colic, and in which röntgenographic examination for stone was negative. The symptom-complex in this class of cases had usually been rather vague in its diagnostic indications, and there had undoubtedly been many instances in which a faulty diagnosis had led to operation for conditions which were not present, the trouble being laid to an appendix, a tube, an ovary, or a gall-bladder. In the class of cases under consideration it was found by Fowler that the injection of a comparatively small amount of solution (averaging only 14 c.c.) into the pelvis of the kidney produced a pain exactly similar to the pain from which the patient suffered; an injection of the unaffected kidney produced a pain which the patient had never felt there before, but identical with that which had been felt on the other side. They had already examined hydronephrotic cases after collargol injections, and in the course of several conferences on the subject of the röntgenographic examination of the various viscera in which mention was made of the fact that he, as a routine, made röntgenographic examinations of the stomach and intestines with the patient in the erect posture, Fowler suggested that in examining these cases of "intermittent hydronephrosis" the collargol be injected first with the patient reclining and a plate made, then the patient placed in the erect posture and a second plate made. While the patient was in the erect posture he was instructed to make various movements of the trunk, such as would be calculated to dislodge a really movable kidney, and at the same time the ureteral catheter was being withdrawn while a further amount of solution was being injected through it, thus showing röntgenographically the changed position of the kidney and demonstrating the appearance of the ureteral kink. This procedure, as far as they could ascertain, had not been made use of prior to their work.

Collaboration Essential in the Diagnosis of Surgical Conditions of the Kidney and Ureter.—Dr. John Hunter Selby of Rochester, Minn., thought that cooperative examination opened up additional possibilities, especially in that large group of abdominal cases seen in daily practice which exhibited an indefinite line of symptoms referable, perhaps, to the appendix, gall-bladder, stomach, duodenum, spine, or genitourinary tract, but with a strong possibility of involvement of the genitourinary tract. Such cases required careful study, and some of them taxed every means at our command before we could approach an accurate diagnosis. In St. Mary's Hospital (Mayo Clinic) all such cases were referred to the röntgen laboratories for examination. The routine examination in this clinic might be described as follows: A full history was taken and a physical examination made. A twenty-four hour specimen of urine was reported on, and, perhaps, a gastric analysis was made—all of which might throw considerable light on the case and yet not clinch the diagnosis. The röntgenologist was then called upon to examine the case, and after the proper preparation of the intestinal tract a set of stereoscopic plates of the upper abdomen and a second set of the lower abdomen and pelvis were made by the rapid method, that is, while the breath was held. If this examination failed to reveal any abnormalities, we had not yet ruled out the genitourinary tract. If, then, in the light of the clinical findings and negative *x*-ray examination, the diagnosis was still under suspicion, the patient went through a second preparation of the intestinal tract and was referred to the cystoscopist the following day. In the meantime the original plates were studied and a consultation was held between the physician in charge, the röntgenologist, and the cystoscopist. This at times furnished the cystoscopist with much-needed information and established a new working basis for the röntgenologist should subsequent events indicate a second *x*-ray examination. The cystoscopist now made his thorough routine examination and he alone might clear up the diagnosis by one of his ingenious methods and thus eliminate the necessity for the "combined examination." He might gather evidence to confirm the original *x*-ray findings or to disprove them. Again, he might find evidence of trouble that had not so far been suspected. Therefore, the indications for the combined examination depended upon the original *x*-ray findings plus the findings by the cystoscopic examination. There were two efficient methods of examining these cases in use: The gravity method and the syringe method. The important factor in each was to avoid overdistending the kidney pelves, the calices, and the ureter. Should overdistension occur, a renal colic might cause a violent contraction, which prevented getting an outline of the pelves in repose. During the attack of colic the patient was restless and even if the exposure was short we seldom got a clear image. The shadow of the pelves in contraction was misleading and valueless. Let one assume that in the original röntgen examination the pelvic plates showed a shadow at the region of the ureteropelvic junction on the right side. Both plates of the stereoscopic set showed it distinctly; one recorded its presence, its appearance, and its apparent location, and called it a "suspicious shadow." The case was referred to the cystoscopist for further examination since one did not dare to risk making a diagnosis on the original plates alone, even when the history and symptoms seemed to justify it. Experience in a large number of these cases had taught one that the most skilful interpretation in many instances was unsafe. Therefore, one was content to call these shadows "suspicious" until one had established their identity and their approximate location. At the subsequent or combined examination one sought not only to locate and identify the calculus, if present, but one endeavored to gain additional information, such as demonstrating the presence of an associated ureteritis, constriction, local dilatation of the ureter, hydroureter, hydronephrosis, pyonephrosis, or deformities. Should the procedure exclude the suspicious shadow as a possible source of trouble and fail to demonstrate any deviations from the normal, the genitourinary tract could be eliminated in the diagnosis. But the combined examination might have demonstrated any one of a number of important surgical conditions; for example, an anatomical or pathological stricture, kink, constriction, tortuosity, an anomaly of the ureter, nephroptosis, pyonephrosis, hydronephrosis, tuberculosis, or chronically inflamed kidney, variation in the shape and contour of the normal pelves and calices, the presence of recognized or amorphous deposits in the kidney, and renal neoplasm. One oftentimes was called upon to rule out the kidney in the case of an abdominal tumor with which the kidney might be easily confused. Here the combined examination was of the greatest value. One could not only locate the position of the kidney and thereby ascertain the relative position of the tumor, but experience, gained by the study of a large number of

collargol plates outlining the renal pelves, had taught one that where the kidney itself was involved by a tumor to any extent one could usually find distinct evidences of it in a clear *x*-ray plate of a carefully injected kidney pelvis. These observations were based upon a study of 1,986 abdominal cases of the type referred to, radiographed during the past eighteen months in St. Mary's Hospital (Mayo Clinic). Of these 300 were examined by the combined method, collargol being used.

Dr. Percy Brown of Boston had had a case which, clinically, was diagnosed as a nephroptosis, but the Dietl's crisis was out of proportion to the ptosis. He made a roentgenogram and found a kink in the ureter. A ptosis was present, but not startling.

Dr. Eugene W. Caldwell of New York City encouraged the cooperation between the surgeon and the röntgenologist. One could not hope to get the best results until one got team work. He would advise Dr. Selby to do more stereoscopic work.

Dr. Charles L. Leonard of Philadelphia said that it was important to look at these plates stereoscopically. He recently located five stones in the lower ureter. The surgeon would not have found the fifth stone if he had not examined the plate stereoscopically.

Röntgen Diagnosis of Position in Pregnancy.—Dr. P. M. Hickey of Detroit, Michigan, said that it was possible to make a Roentgen diagnosis of the position of the fetus in utero without apparent injury to the mother or fetus. The differential diagnosis between single and multiple pregnancy could be made with certainty. The cases be investigated went on to term and normal delivery. Careful examination of the child failed to reveal anything indicative of damage done by the ray.

Pulmonary Metastases from Papillomatous Cyst of Ovary.—Dr. Hollis E. Potter of Chicago said that eight years ago a woman was operated on for papillomatous cyst of the right ovary. Regional recurrence necessitated a second and a third operation, six and five years ago, respectively. One year ago a small mass was removed from the right groin. At present there were symptoms and signs pointing to a pulmonary involvement. The roentgenogram cleared up a condition which could not be diagnosticated in any other way. Over the central portion of the left lung was a mass obscuring the heart. It apparently occupied one-half of the left side of the thorax. In the right lung was a mass the size of an orange. There was no pulsation. A diagnosis of cyst was made, but the case was considered inoperable.

Relation of Röntgen Laboratory to the Medical School.—Dr. Eugene W. Caldwell of New York thought that there was at present a lack of cooperation between the röntgen laboratory and the medical college. Five or six schools were beyond criticism in this respect. Most schools had laboratories which were useless and dangerous. In many hospitals a photographer or druggist ran the *x*-ray machine. Nearly all the development in röntgenology had been made by private individuals at their own expense. The results of röntgen examination should be checked up by the röntgenologist in cooperation with the clinician and the pathologist. The hospital and the medical school should make the specialty attractive to medical men who possessed the necessary qualifications to do efficient work.

The Use of the Fluoroscope as a Guide for the Bronchoscope and Esophagoscope in the Removal of Foreign Bodies.—Dr. C. F. Bowen of Columbus, Ohio, said that the successful outcome of a foreign body case depended, first, upon the diagnosis, and, second, upon the method of procedure. In all cases where a foreign body was either swallowed or inspired, an *x*-ray examination should be made by a competent person before any attempt at its removal. If the foreign body was dense enough to be revealed on an *x*-ray plate, the diagnosis by this means was easy, but even in those cases where a vegetable foreign substance itself was not opaque to the *x*-ray, a great deal of information could still be obtained. A grain of corn, for instance, lodged in the bronchus would not cast a shadow on a photographic plate, but its presence could usually be determined by the slight changes in the lung itself, caused by a localized pneumonia, or by a blocking up of certain air cells. The same was true of vegetable foreign bodies in the esophagus, for while the body itself could not be seen, information, especially as to its location, could be obtained by giving the patient bismuth either in the form of a capsule or in gruel, and watching the passage of this preparation down the esophagus with the fluoroscope. If a foreign body was present, the bismuth would be stopped, or at least hesitate at the obstruction. He believed that it was a rare case in which an *x*-ray examination would not be of some service in the hands of one skilled in this work. He had removed quite a number of foreign bodies from the esophagus by means of the esophagoscope, and while their removal had, as a rule, been accomplished without difficulty, he had always taken the precaution of placing the patient upon his *x*-ray operating table, so that if he had failed for any reason to have at once located the foreign body with the esophagoscope, he could have used the *x*-ray and fluoroscope in guiding the esophagoscope towards the foreign body. This was a precaution which he had never heard of being used before and which he thought should be used in every case. No attempt should be made to either use the bronchoscope or the esophagoscope without having an *x*-ray apparatus close at hand, and since the *x*-ray played such an important part in the diagnosis and treatment of this class of cases, he believed that this work should be done by the *x*-ray operator himself, who had a knowledge of surgery, rather than by a surgeon with an *x*-ray operator as an assistant.

The Abdominal Viscera in Autointoxication and Autoinfection.—Dr. Joel E. Goldthwait of Boston said that the important viscera of the body were in the chest and abdomen, except the brain, and the proper relation of these organs, one to the other, determined the health of the individual. The röntgen ray was of the greatest assistance in determining the position of these organs as well as the disturbances that might result from a malposition of one or more organs. A displaced organ might not suffer of itself, but it might push some other organ out of place and cause that organ to suffer. In the quadruped the abdominal organs hung freely from the backbone, and there was no interference of one with the other. In the biped this relation was changed. One individual in five was born with the organs of a quadruped, although that did not necessarily do any harm in itself, and that was one of the points he wanted to emphasize. For instance, these patients had sacroiliac strain because they were standing out of poise; but that in itself was a cause of visceral strain. If the viscera were not hung right it led to a drooped posture. In one such case he saw the stomach was down in the pelvis. Then, the stomach could not unload itself unless the patient assumed a certain posture. The transverse colon very frequently was dropped away down. There might be a loose liver or loose kidneys. In all these cases there was an absence of retroperitoneal fat. It either never was present or it was absorbed. There was no shelf for the kidney. Sewing the stomach or any other one loose organ into place did not give these patients any relief, except for a short time only. All the loose organs must be replaced and that could not be done by suturing. There were certain earmarks which accompanied these conditions so that this class of patients was easily recognized at sight. Ptosis of the hepatic flexure of the colon was very distressing.

The progress of the intestinal contents in these cases was interfered with seriously, and the result was autointoxication. In the work he had been carrying on almost every combination had been found—a firmly attached ascending colon, with a free descending colon, and vice versa, or any part of the colon might be free or attached. The fluid part of the intestinal content was absorbed and the waste was worked together into a bolus which refused to pass onward. A patient might have a regular bowel movement and yet in the pockets and pouches formed in the walls of the colon there might be fecal matter so firmly caked that a blunt dissector was necessary to loosen it. The röntgen ray was of the greatest value in diagnosticating these conditions; in fact, the diagnosis could not be made without it. One could not relieve these patients until one got the viscera to work right. With proper treatment one could replace these organs, and the rontgen ray would aid in checking up the results of the treatment. These patients must be nourished until one could see the retroperitoneal fat. Exercises must be prescribed. The organs could not be replaced when the chest was narrow or the body was stooped. One must make it possible to have the ribs flare so that the organs could stay in place. The posture was the result of the ptosis. When the ribs slanted inward and downward, the liver and stomach were pushed out of place, which in turn interfered with the position of the colon and other viscera. That was an acquired condition. These patients must be fed properly, live properly, exercise, and observe certain rules of posture.

Dr. Percy Brown of Boston said that this paper opened up an interesting field of work. Hertz of England wrote an admirable book on constipation. He called the condition in the colon, described by Dr. Goldthwait, a hyperperistalsis, where apparently the succus entericus was formed in increased amount; everything was ready for the waste, but none came. The so-called "gredy gut," of Hertz, was an excessive contraction of the circular muscle fibers of the intestine. When the food finally came, it was dry and the constriction of these circular fibers squeezed the food, and it became sapless, hard and scybalous. Dr. Goldthwait's investigations were of the greatest value in directing attention to the probable cause of these conditions and their treatment.

Dr. George E. Pfahler of Philadelphia said that Jordan recently called attention to a kink in the duodenum at its junction with the jejunum, which might give rise to a spasmodic condition of the bowel leading to pain, ulcers, and sometimes to adhesions. This condition was easily overlooked; therefore, one must make a series of examinations and do considerable fluoroscopic work. He had seen adhesions betwen the descending and transverse colons and sigmoid caused pain. Sometimes patients were operated on for appendicitis, and then they failed to get relief from their symptoms. It was a problem just what to do in these cases.

Dr. Charles L. Leonard of Philadelphia in one of these obscure cases, found adhesions and a stricture of the ileum which had caused the patient much pain, and which one surgeon had diagnosed as appendicitis.

Dr. F. H. Baetjer of Baltimore had seen two cases in which the abdominal viscera were in the pelvis, although the splenic flexure was held firmly in its normal position.

Dr. C. E. Coon of Syracuse said that if one could show that there was a retention of the intestinal contents due to malposition of the abdominal viscera, many of these chronic sufferers would be able to get relief.

Dr. Roland Hammond of Providence, R. I., had observed many times that while we might not change the position of the viscera by supportive and stimulative treatment, we often relieved the patient of symptoms by simply taking off the strain—the sag. By restoring the normal physiology of an organ by supportive apparatus and stimulating exercises, we were doing all that could be done and practically were effecting a cure.

Dr. J. E. Goldthwait of Boston said that in studying these cases one must use his good sense and not see only the colon or stomach, but the human being, with a lot of organs whose balance must be worked out. He believed that one could help these patients. These were human problems, capable of solution by human intelligence, otherwise the scheme of the universe was wrong—and it was not wrong. One could not give these patients normal ligaments, but we could give them normal function. If one operated to replace an organ, the patient would feel better for a while, and then got much worse again, as food was taken. If there was a special condition for which suture was desirable, all right, but it must be followed up by other treatment. The same was true of the operations done for drainage of the bowel. The short-circuiting of the bowel which Lane and others were doing was faulty, in that they saw only the colon, and not the other abdominal viscera. It was not only the colon which was causing the mischief. One could not do very much for the acquired cases. As for the congenital cases, if one would make the patients suffering from acquired conditions as nearly normal as possible, one would gradually lessen the number of congenital cases. It was simply a question of race improvement. If one could get these organs to work right, the patient would get well. The patients should be fed judiciously and well, exercised, trained and taught how to stand correctly, and their posture should be improved; then one would get good results.

MEDICAL ASSOCIATION OF THE SOUTHWEST.

Sixth Annual Meeting, Held at Oklahoma City, Okla., October 10 and 11, 1911.

The President, Dr. M. L. Perry of Parsons, Kan., in the Chair.

President's Address: Management of the Nervous Child.—Dr. M. L. Perry of Parsons, Kan., stated that the nervous child was the father of the neurotic and neurasthenic adult, but granting this potentiality it was also true that proper care during the developmental period would often prevent the occurrence of actual disease at a later date. It was not only the functional nervous conditions whose seed was sown in early life, but many preventable organic affections originated within or developed later on the groundwork of nervous instability acquired in infancy or during the first few years. Under the term "nervous child" he included several types differing from one another in some particulars, but all showing evidence of a more or less deviation from the evenly balanced, well-adjusted, normal nervous system. He included in this category: 1. The precocious child, with its highly organized but poorly balanced nervous mechanism, who was capable of rather extraordinary mental efforts along certain lines, but prone to an early breakdown. 2. The quick, alert, restless child, whose whole nervous system appeared to be hypersensitive, whose mental faculties were so active that concentration was difficult, and who was largely reflex in type. 3. The shrinking and abnormally timid child, who was weak in nerve force, and therefore easily exhausted. 4. The backward child, who was slowed up mentally either on account of defective organs of special sense, or an inherent defect in correlating sense perceptions and in forming ideas. In the care of such children the influence of nutrition and dietetics was of paramount importance. Malnutrition was a potent factor in the development of nervousness as well as in aggravating the condition when it existed. Measures directed toward maternal feeding and providing the poor with the means for carrying out artifi-

cial feeding, according to the most rational methods, were suggested as the best means of prophylaxis. There was a crying need of reform in our educational system. A more thorough inspection of school children by physicians or some one competent to detect defects and disease should be made, and school authorities should recognize the necessity of special class work in the public schools for defective children not ordinarily classified as feebleminded. The greatest asset of any nation was its children. No effort should be spared that made for their mental and physical betterment, for on their stability depended very largely the future prosperity and progress of the nation and the race.

Ulcers of the Stomach and Duodenum, with Report of a Case of Duodenal Ulcer.—Dr. C. B. Hardin of Kansas City, Mo., stated that the etiology of ulcers of the stomach and duodenum was obscure. Early diagnosis and early efforts at control were the dicta of the present-day treatment of ulcers of the stomach and duodenum. Very important was the differential diagnosis between ulcers of those structures and conditions closely simulating them from the standpoint of symptomatology, as cholelithiasis, cholecystitis, malignancy, appendicitis, affections of the kidney, etc. The majority of gastric ulcers at or near the pylorus which gave rise to typical symptoms were near the greater curvature, but especially so in the absence of complications. The control of pain was most important in the management of peptic ulcers. The relief afforded by medicine certainly delayed early surgery in ulcers of the stomach and duodenum. He thought in the light afforded us at the present time, when definiteness of diagnosis was approximately certain, that all cases where the physical condition of the patients would warrant should be early relieved by surgical operation.

Pancreatitis: Suggestions as to Etiology and Surgical Treatment.—Dr. A. L. Blesh of Oklahoma City drew the following conclusions: 1. Chronic pancreatitis in association with bile track infections was not uncommon. Without this association it was comparatively rare. 2. When present, while it added more or less to the symptom-complex, the clinical syndrome was so overshadowed by gall tract infection that it was rarely ever diagnosed in the absence of a palpable enlargement of the head of the pancreas. 3. Both pancreatic and gall tract infections might be due to an infection from below, and this in turn might depend upon a malformed colon, causing a high degree of coprostasis. 4. The frequent association of pancreatic biliary infections, duodenopyloric ulcers and chronic appendicitis was at least suggestive of a common exciting cause. 5. In this train of sequences the fact that we never encountered an acute, but always a chronic, type of appendicitis was of great theoretical and practical importance as, at least, hinting at the etiology. 6. Direct biliary and pancreatic drainage or simple gastrojejunostomy would not always cure the respective diseases, but would always give temporary relief. This fact suggested that these operations did not always measure up to the pathology and etiology. 7. In properly selected cases Lane's operation should be added. 8. If done in time, perhaps the latter, in properly selected cases, would be sufficient.

Dr. Bacon Saunders of Fort Worth, Tex., said that in common with other surgeons he had noted the various conditions spoken of by the essayist, but there was one thing that impressed him, namely, the marked tendency in searching for something wonderful every time the surgeon opened the abdomen for the relief of some intraabdominal condition. It would be better not to look for these wonderful things when one operated. He had straightened out many of these kinks by removing the apparent pathological condition. He had cured many cases of chronic pancreatitis by drainage of the biliary tract. He had had a great many cases in which things looked curious, but after removing well-known pathological conditions the patients had recovered.

Dr. J. H. Riddell of Enterprise, Kan., said that when a surgeon opened the abdomen and found bands of adhesions, if they had nothing to do with the pathological condition he was going to correct, they should not be separated. If a surgeon should open his abdomen he would not want him to remove any section of his anatomy that looked right for fear it might give him subsequent trouble.

Dr. J. F. Binnie of Kansas City, Mo., agreed with Dr. Saunders that we should only remove the real pathological condition that was causing the trouble; that we should not take out an appendix that was not causing trouble.

Dr. Howard Hill of Kansas City, Mo., said he had been having a series of cases of gall-bladder trouble, and in twelve out of thirty or forty cases there had been inflammation of the pancreas, and in most of them the appendix was affected primarily.

Dr. Blesh, in closing, said he had had the uncomfortable experience of having had uncured cases come to him in which he thought he had extirpated the disease. He asked whether the surgeon always removed the disease when he thought he did. The pathology must always be coupled with the etiology, and the man who forgot etiology in dealing with a pathological condition was surely going to have some cases come back to him.

Retrocecal Appendicitis.—Dr. J. N. Jackson of Kansas City, Mo., said there were two anatomical positions of the appendix that were extremely unusual, and when the appendix was situated in either of these places and was inflamed it gave rise to a different set of symptoms and led to delay in diagnosis. These were the retroperitoneal and retrocecal types of appendicitis. He gave the symptoms of each type. In the surgical treatment in the retrocecal type the incision should be made farther out than usual to avoid infection of the peritoneal cavity, possibly splitting the outer fold of the mesocolon so as to turn the colon over to the inside to get the appendix situated behind. After removing the appendix, sometimes there was an abscess cavity to contend with, and the patient was subject to the usual infection following a cellulitis. Instead of inserting a drainage tube, the cavity should be thoroughly disinfected with strong iodine or carbolic acid, followed by alcohol and free packing of the cavity. In cases where an abscess had ceased to be local and had spread behind the gut and peritoneum, spread up under the colon, a counter-opening should be made to get drainage at the most dependent point.

Dr. Bacon Saunders of Fort Worth, Tex., stated that he read a paper on this subject in 1892 before the Southern Surgical and Gynecological Association. In the cases of appendicitis under discussion the symptoms were so slight that they were frequently overlooked, but the paitent did not get well. He developed a septic condition and the surgeon saw him one or two weeks afterward and found out what the trouble was. In these cases he usually made the incision entirely outside of the colon, and in a large percentage of them it was necessary to resort to posterior drainage. A small drain would not do much good.

Dr. Crowell said he had never seen a case in which the appendix was beneath the peritoneum. He was satisfied that one of his patients, a girl of twelve, who was subjected to the Ochsner treatment for twelve or fourteen days, had a retrocecal abscess. There was a very much distended space in this region. He cleaned out the abscess thoroughly, but the patient died immediately. He believed that death followed because in opening up and disturbing this abscess so effectually at the time he liberated an undue number of toxins. He believed that we frequently had sudden deaths following large abscesses by disturbing the relations and having absorption of the toxins take place Had he opened the abscess in this case in a limited way

and drained, he felt certain that the girl would have recovered.

Dr. John G. Sheldon of Kansas City, Mo., said that in some of these cases, where the appendix was retroperitoneally located, there might be involvement of the ureters. Indeed, the speaker said, it was almost impossible to imagine what might not happen in some of these cases.

Dr. J. D. Walker of Caney, I. T., related the case of a patient who had the typical symptoms of appendicitis, but on opening the abdomen no inflammation could be found. In tracing the ascending colon down to its termination and finding its union with the small intestine coming across, he found an organ about the size of a goose quill, which he took to be the appendix. This he removed and the patient recovered.

Dr. J. M. Inge of Denton, Tex., said he thought it was important in these retroperitoneal conditions to go in back of the peritoneum, but how many surgeons in making an incision went far enough back to avoid the peritoneum? In some of these cases it was not good surgery to break up dense adhesions in the effort to find the appendix and remove it.

Postoperative Ileus: Report of a Case Relieved by Intestinal Puncture.—Dr. Leroy Long of McAlester, Okla., said that the patient entered the operating room with a temperature of 98.2°, pulse 62, and of good quality. Operation was done with the patient in the Trendelenburg position. When the abdomen was opened there was found on the right side a cystic tumor involving both tube and ovary. The tumor and both the tube and the ovary were removed. The left tube was found distended and tense. It was probably three-quarters of an inch in diameter. There were no adhesions about it, and it was easily removed without disturbing the ovary, which was left. This tube, when opened subsequently, was found to contain a fetus. The round ligaments were shortened on account of a retrodisplacement of the uterus, and the vermiform appendix was removed. Several hours later intestinal obstruction occurred, which was promptly relieved by puncture of the intestine.

Dr. L. S. Willour of Atoka said that some authority had recommended that drainage of the intestine be established in these cases of ileus by means of the Murphy button. The technique of this was as follows: One end was to be inserted in a catheter, an opening made in the intestine, and the Murphy button brought together, and in this way drainage could be had without the contents escaping about the wound.

Dr. Howard Hill of Kansas City, Mo., stated that in cases of ileus he had thought that the administration of one-fiftieth of a grain of eserine had helped these patients to recover tone if they were seen early and before much distention of the abdomen had taken place.

Dr. J. N. Jackson of Kansas City, Mo., said that it was his privilege to have seen only three cases of well-defined Lane's kink, and a liberation or straightening out of the kink had resulted in the relief of the localized intestinal obstruction.

Dr. H. C. Crowell of Kansas City, Mo., stated that in the past surgeons physicked these patients too much. There was no reason why this should be done, and now it was rare for him to do it. If he physicked these patients at all, it was three days before operation in order to remove the flora from the intestinal tract, which otherwise would cause distention and fermentation and ileus and the paralysis which would follow. He was convinced there was some benefit to be derived from the use of eserine in these cases after symptoms of distention had manifested themselves. He had also thought that he derived benefit from the use of physostigmine, and these patients as a rule had recovered.

(To be continued.)

STATE BOARD EXAMINATION QUESTIONS.

Oklahoma Board of Medical Examiners.

July 11, 1911.

ANATOMY.

1. Name the parts common to all vertebræ. Name and describe the peculiar cervical vertebræ.
2. Describe the elbow joint.
3. Give origin, insertion, and nerve supply of the coracobrachialis muscle.
4. Describe the thoracic duct, giving origin and termination.
5. Describe the duodenum.
6. Briefly describe the arch of the aorta and name its branches.
7. Give the origin and name the principal branches of the musculospiral nerve.
8. Name the principal branches of the cervical ganglia of the sympathetic.
9. Give the histological difference between a cerebrospinal and a sympathetic nerve fiber.
10. Locate and give histological structure of the intestinal villi.

PHYSIOLOGY.

1. Name three kinds of impulses that pass over an anterior nerve root.
2. Trace a motor impulse from the cortex to a muscle of the face.
3. In what part of the brain would the impulse arise in the above question?
4. In the knee joint what kinds of tissue are represented in (*a*) the capsular ligament, (*b*) the semilunar cartilage, (*c*) the entire extremity of the femur?
5. (*a*) What nerves control the distribution of the blood, (*b*) the heart's action?
6. (*a*) By what organs is most of the carbon excreted, (*b*) most of the nitrogen?
7. Name all the nerves involved in sneezing.
8. Name five things that affect the character of a muscle contraction.
9. Name six secreting organs and an important characteristic in the process of two of them.
10. Name four purposes for taking food.

MATERIA MEDICA AND THERAPEUTICS.

1. Give indications for use of aconite.
2. Give symptoms and treatment of diabetes mellitus.
3. Give indications for use of belladonna.
4. Give etiology, symptoms, and treatment of pericarditis.
5. Give indications for use of quinine.
6. Discuss palpitation of the heart.
7. Give indications for use of veratrum viride.
8. Differentiate a functional derangement from an organic lesion.
9. Give indications for use of nux vomica.
10. Diagnose and treat diphtheria.

CHEMISTRY.

1. What is an element? Name ten elements existing uncombined in nature.
2. Name the abnormal constituents of urine and the normal specific gravity of urine.
3. Define (*a*) precipitate, (*b*) filtration, (*c*) evaporation, (*d*) endomosis, (*e*) alloy.
4. How would you determine, chemically, whether a urinary deposit were composed of urates or phosphates?
5. Complete the equation:

$$2SO_2 + H_2O + HNO_3 = N_2O_3 + (\quad).$$

6. Mention antidotes applicable in case of poisoning from iodine.
7. Chemically, what is albumin?
8. Mention some of the important physical, physiological, and chemical properties of ptomaines.
9. What are the antidotes for bichloride of mercury?
10. Describe your mode of procedure in making a chemical examination of suspected urine.

TOXICOLOGY AND MEDICAL JURISPRUDENCE.

1. Give symptoms of chronic mercurial poisoning.
2. How does chloral hydrate cause death?
3. What alkaline antidotes are most likely to be at hand in a case of emergency poisoning?
4. Give symptoms caused by eating poisonous fungi. In fatal cases how soon does death occur?
5. Give symptoms of acute and chronic arsenical poisoning.

6. Give symptoms of prussic acid poisoning and the appearance of the body after death from such cases.
7. Define "unprofessional conduct."
8. When may abortion be legally permitted?
9. In case of poisoning, the nature of the poison being unknown, how should the case be handled?
10. Give symptoms of aconite poisoning, of lead poisoning.

BACTERIOLOGY.

1. Name three ways by which you can prove that a microorganism is the cause of a disease.
2. Divide bacteria into three groups and explain each group.
3. Name the bacterium found in erysipelas and how does it spread?
4. Differentiate between *Bacillus typhosus* and *Bacillus coli communis*.
5. Give brief history of *Bacillus tetani* since 1884.

PATHOLOGY.

1. Describe the pathology of lung tissue in lobar pneumonia.
2. Give the pathology of acute yellow atrophy of the liver.
3. What is parenchymatous nephritis? Give its pathology.
4. Describe the pathology of tabes dorsalis.
5. Give brief history and pathology of senile gangrene.
6. When and where found: (*a*) Mucoid degeneration, (*b*) colloid degeneration, (*c*) hyaline degeneration?
7. Name four conditions in which tumors are distinguished, and give example of each.
8. Name three varieties of inflammation, give process of each.
9. Name three causes for arterial hyperemia. Give example of each.
10. Differentiate between thrombi and embolism.

PHYSICAL DIAGNOSIS.

1. Give physical signs of malaria.
2. Give physical signs of anemia.
3. Give physical signs of acute follicular tonsillitis.
4. Differentiate malaria from anemia.
5. Give physical signs of spasmodic croup.
6. Differentiate spasmodic croup from follicular tonsillitis.
7. Give physical signs of acute catarrhal dysentery.
8. Give physical signs of enteralgia (colic).
9. Give physical signs of a typical case of typhoid fever.
10. Differentiate typhoid fever from malarial fever.

OBSTETRICS AND HYGIENE.

1. Define parturition.
2. When does the second stage of labor begin? Give your management of the second and third stages of normal labor.
3. What causes constipation during pregnancy? Give your treatment of same.
4. Diagnose a case of pregnancy at the end of the fourth month.
5. Give care of a seven-months' child when without the hospital advantages.
6. How would you determine the death of the fetus *in utero* after the fifth month?
7. Give treatment of breech presentation.
8. Give indication for producing podalic version. What precautions are necessary?
9. How is the typhoid germ transmitted? Give instructions to prevent spread of disease.
10. Give hygienic treatment of summer diarrhea in children.

GYNECOLOGY.

1. Describe and treat urethral caruncle.
2. Define prolapsus uteri, giving etiology, pathology, and treatment.
3. Give etiology and diagnosis of pyosalpinx.
4. Define vicarious menstruation.
5. Give symptoms of acute pelvic peritonitis.
6. Define and treat pruritus vulvæ.
7. What conditions may result from gonorrhea in women?
8. Diagnose ruptured tubal pregnancy.
9. Define amenorrhea, dysmenorrhea, menorrhagia.
10. What is subinvolution of the uterus? Give treatment.

SURGERY.

1. What are the symptoms of septic surgical fever?
2. What is the differential diagnosis between septicemia and pyemia?
3. What is hydrophobia and how is it treated?
4. What are the contraindications respectively to the use of the three principal general anesthetics?
5. What are the causes of secondary hemorrhage?
6. Name the varieties of shoulder joint dislocation.
7. How are dislocations distinguished from fractures?
8. What is Colles' fracture? How would you treat it?
9. Give the method of inserting Wyeth's pins for amputation at the hip joint.
10. What tissues are divided in the operation of oblique inguinal hernia?

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

OKLAHOMA BOARD OF MEDICAL EXAMINERS.

July 11, 1911.

ANATOMY.

1. *Parts common to all vertebræ:* Body and neural arch; this latter is formed of two pedicles, two laminæ, and seven processes (four articular, two transverse, and one spinous.

Peculiar cervical vertebræ are: First, second, and seventh. See Cunningham's "Anatomy" (1909), page 79; or Gray's "Anatomy" (1910), page 50.

2. See Cunningham's "Anatomy" (1909), page 279; or Gray's Anatomy (1910), page 306.

3. CORACOBRACHIALIS. *Origin:* Coracoid process of scapula; *insertion:* Middle of inner surface of humerus; *nerve supply:* Musculocutaneous.

4. The *thoracic duct* extends from the second lumbar vertebra, where it commences by a dilatation, the *receptaculum chyli*, to junction of left internal jugular with left subclavian vein. The abdominal part is placed on the front of the body of the second lumbar vertebra, behind and to the right side of the aorta and on the inner side of the right crus; it then enters the thorax through aortic opening, on the right side of aorta, lying between it and the vena azygos major, and passes upward to right of aorta on right intercostal vessels. Opposite the fourth dorsal vertebra it passes to the left behind arch, and runs along the left side of the esophagus, behind the left common carotid artery. At the level of the seventh cervical vertebra it turns outward, and, passing behind left internal jugular and crossing first part of left subclavian artery, arches over the apex of the left pleura to open at the angle of union of the left internal jugular and left subclavian veins. (From *Aids to Anatomy.*)

5. See Cunningham's "Anatomy" (1909), page 1065; or Gray's "Anatomy" (1910), page 1283.

6. See Cunningham's "Anatomy" (1909), page 797; or Gray's "Anatomy" (1910), page 582. *Branches:* Innominate, left common carotid, and left subclavian.

7. MUSCULOSPIRAL NERVE. *Origin:* Posterior cord of brachial plexus. *Branches:* Muscular, cutaneous, radial, posterior interosseous.

8. See Cunningham's "Anatomy" (1909), page 706; or Gray's "Anatomy" (1910), page 1069.

9. *Cerebrospinal nerve fibres* are medullated; and consist of an axis cylinder, a medullary sheath, and a neurilemma. *Sympathetic nerve fibers* are mostly non-medullated; and consist of an axis cylinder and a neurilemma, but have no medullary sheath.

10. See Cunningham's "Anatomy" (1909), page 1062; or Gray's "Anatomy" (1910), page 1292.

PHYSIOLOGY.

1. Motor, vasomotor, and secretory impulses may pass over an anterior nerve root.

2. The impulse would travel from the cortex cerebri, through the corona radiata, internal capsule, crus, pons, medulla, and the facial nerve.

3. The impulse would arise in the cortex cerebri, in the lower third of the frontal convolution.

4. *In the capsular ligament,* white fibrous tissue; *in the semilunar cartilage,* fibro-cartilage, and hyaline cartilage; *the extremity of the femur,* bone and cartilage.

5. (*a*) Vasomotor (vasoconstrictor and vasodilator); (*b*) Vagus, and sympathetic.

6. (*a*) Most of the *carbon* is excreted by the lungs; (*b*) most of the *nitrogen* is excreted by the kidneys.

7. In *sneezing,* the *afferent* nerve is generally the nasal branch of the first division of the fifth cranial nerve; the vagus and glossopharyngeal nerves are also involved. The *efferent* nerves are the phrenic, vagus, and intercostal nerves; the spinal nerves to the extraordinary respiratory muscles and the facial, spinal accessory and hypoglossal nerves also assist.

8. (1) The character of the muscles, (2) the character of the stimulus; (3) the load; (4) temperature; (5) previous stimulation.

9. *Six secreting organs:* (1) Lacrimal glands; (2) testes; (3) mammary glands; (4) liver; (5) salivary glands; (6) glands of stomach. The mammary glands only secrete under the stimulus of pregnancy and labor; and the salivary glands only secrete as the result of suitable reflex stimulation of the secretory nerves.

10. *Four purposes for taking food:* (1) For the growth of the tissues and organs of the body; (2) for the repair of waste; (3) to supply energy; (4) to supply heat.

MATERIA MEDICA AND THERAPEUTICS.

1. *Indications for use of aconite:* Fevers, some inflammatory conditions, in high arterial tension, in nervous palpitation of the heart, and congestive dysmenorrhea; also externally for neuralgia, pruritus, herpes, chilblains, etc.

2. See French's "Practice of Medicine" (1910), pages 970 and 974; or Osler's "Practice of Medicine" (1909), pages 414 and 420.

3. *Indications for use of belladonna:* To relieve pain, relax spasm, check sweating, as a mydriatic, for night sweats, to check griping of purgatives; in asthma, to check fevers, in heart disease, shock and collapse, acute coryza, urinary incontinence, chordee, low delirium of fevers, mania, alcoholism; as an antigalactagogue, spasmodic cough.

4. See French's "Practice of Medicine" (1910), pages 567, 569, and 573; or Osler's "Practice of Medicine" (1909), pages 775, 776, 779, and 782.

5. *Indications for use of quinine:* In malaria; as a tonic; in influenza, in dyspepsia, in asthma; as an antipyretic; and locally, for sores in diphtheria, and in hay fever.

6. See French's "Practice of Medicine" (1910), page 627; or Osler's "Practice of Medicine" (1909), page 832.

7. *Indications for use of veratrum viride:* "As a circulatory depressant, given early, in croupous pneumonia, pleurisy, hepatitis, maniacal delirium, etc., with strong, bounding pulse and other sthenic conditions; in puerperal convulsions and the early stage of peritonitis, phlebitis, and other inflammatory affections of the puerperal state; also acute rheumatism, tonsillitis, aneurysm, and wounds of the head, pericardium, and peritoneum."—(Wilcox, *Materia Medica.*)

8. In a *functional derangement* the functions of a tissue or organ are out of order, but no structural defect can be discovered; in an organic lesion some structural defect may be detected.

Organic murmurs are due to stenosis or incompetency of one or more of the valves of the heart.

Functional murmurs are not due to valvular disease.

Organic murmurs may be systolic or diastolic; may be accompanied by marked dilatation or hypertrophy, and there will probably be a history of rheumatism or of some other disease capable of producing endocarditis. Whereas a murmur, usually systolic, soft, and blowing, heard best over the pulmonic area, associated with evidences of chlorosis or anemia, and affected by the position of the patient, is a *hemic* or *functional* murmur, and denotes as a rule an impoverished condition of the blood.

9. *Indications for the use of nux vomica:* As a general tonic or bitter; in indigestion, cardiac depression, impaired peristalsis, pneumonia, phthisis, amenorrhea, dysmenorrhea, impotence, some forms of paralysis, chorea, epilepsy, neuralgia, alcoholism, and urinary incontinence.

10. See French's "Practice of Medicine" (1910), pages 184, 191, and 195; or Osler's "Practice of Medicine" (1909), pages 200, 205, and 207.

CHEMISTRY.

1. *An element* is a kind of substance which cannot, by any known means, be split up into dissimilar substances.

Ten elements existing uncombined in nature: Oxygen, hydrogen, nitrogen, carbon, sulphur, arsenic, antimony, bismuth, copper, lead.

2. *Abnormal constituents of urine:* Albumin, sugar, blood, pus, acetone, bile, mucus, casts, bacteria, parasites. The normal specific gravity of urine is about 1015 to 1025.

3. A *precipitate* is the deposit of a solid separated out from a solution.

Filtration is the process of passing a liquid through a filter.

Evaporation is the process by which a substance passes from the liquid to the gaseous state.

Endosmosis is osmosis inwards.

Alloy is a mixture of two or more metals.

4. Urates disappear on heating the urine containing them, while a deposit of phosphates is rendered more abundant by heating. The addition of acid dissolves the phosphates, but has little effect on the urates.

5. $2SO_2 + H_2O + 2HNO_3 = N_2O_3 + 2H_2SO_4$.

6. *Antidotes for iodine poisoning:* Starches in solution, or sodium thiosulphate, or sodium carbonate, or bicarbonate.

7. Chemically, *albumin* is a form of proteid, characterized by being soluble in water and in saline solution, coagulable by heat or by saturating a solution with ammonium sulphate.

8. *Physical:* Some ptomaines are liquid, oily and volatile, others are fixed and crystalline.

Physiological: Some ptomaines are poisonous, some are not; some are of animal origin, some of vegetable; most cause dilatation of pupil, convulsions, slowed heart beat and respiration, vasomotor paralysis.

Chemical: Some are strongly alkaline and basic, others only feebly so; some are prone to oxidation and are active reducing agents, others are stable.

9. *Antidotes of bichloride of mercury:* White of egg, or milk, in moderate quantity, followed by an emetic.

10. See French's "Practice of Medicine" (1910), pages 1233, etc.

TOXICOLOGY AND MEDICAL JURISPRUDENCE.

1. *Symptoms of chronic mercurial poisoning:* Salivation; tremor, first of arms and hands, then of legs and trunk; hypersensitiveness; insomnia; irregular heart action; anemia; cachexia; loss of teeth; emaciation; and necrosis of jaws.

2. In poisoning by chloral hydrate death is said to be due to failure of respiration and sometimes to pulmonary edema; but the matter is not definitely settled.

3. Magnesia, carbonate and bicarbonate of sodium, chalk, limewater, sulphate of magnesium or sodium, soap and water, milk, and white of egg.

4. *Eating of poisonous fungi* may cause: Nausea, thirst, abdominal pain, gastrointestinal irritation with vomiting and purging, fainting, convulsions, small rapid pulse, dilated pupils, delirium, stupor, and death. In fatal cases death usually occurs within twenty-four hours.

5. The *symptoms of acute arsenical poisoning:* Nausea and faintness, severe burning pain in the stomach, persistent vomiting of matters, sometimes brown or gray, or streaked with blood, or green; purging, and cramps in the legs.

Symptoms of chronic arsenical poisoning: Inflammation of the conjunctivæ, with intolerance of light. Irritation of the skin, accompanied by an eruption (eczema arsenicale); local paralyses; great weakness and emaciation; exfoliation of the cuticle and falling out of the hair.

6. *Symptoms of prussic acid poisoning:* "Its action is always rapid. Relatively small doses cause an immediate sense of constriction of the throat, followed in one or two minutes by sense of pressure in the head, vertigo, confusion of intellect, and loss of muscular power. The pulse is quick, the respiration slow and stertorous. Tetanic convulsions and involuntary discharges of urine and feces occur, followed by paralysis. Death follows, in from two hours to two days, from asphyxia. When large doses are taken no subjective symptoms are observed. The patient loses consciousness in less than one minute. There is a short convulsive seizure, usually accompanied by evacuation of feces, after which the patient lies perfectly still, with no sign of life, save an almost imperceptible pulse and infrequent spasmodic respiratory efforts, in which inspiration is short and expiration protracted. Death follows in from five to twenty minutes."—(Witthaus' *Essentials of Chemistry.*)

Post-mortem appearance: "The face is usually pale or cyanosed, the eyes glistening and staring, the blood-vessels of the neck and head turgid. Bright red spots may be noticed on the surface of the body. The blood in the superficial vessels is red, while, unless the dose has been excessive, that in the large vessels is dark. If the dose has been very large all the blood may be arterial in appearance. The poison destroys the power of the blood to decompose hydrogen peroxide. The odor of the acid may be observed soon after death unless overpowered by stronger odors, as tobacco, products of putrefaction, etc. Should the odor have disappeared in other organs it may frequently be found in the brain, as that organ does not undergo decomposition so early. The cerebral vessels are generally congested; in fact, the symptoms are very similar to those of asphyxiation from any other cause."—(Riley's *Toxicology.*)

7. *Unprofessional conduct* may be said to be anything which contravenes the ethical duty which the medical practitioner owes to his profession.

8. Conditions warranting the induction of abortion: (1) Certain pelvic deformities, (2) placenta prævia, (3) pernicious anemia, (4) toxemia of pregnancy, (5) habitual death of the fetus toward the end of pregnancy, (6) hydatiform mole, (7) habitually large fetal head.

9. The first thing to do is to remove as much as possible of the unabsorbed poison, give an emetic (apomorphin hydrochlorid), and also wash out the stomach except when a corrosive has been taken. White of egg and water may be given. Then combat symptoms as they arise, try to prevent shock; artificial respiration, warmth, stimulants, etc., may be indicated.

10. *Symptoms of aconite poisoning* usually manifest themselves within a few minutes; sometimes are delayed for an hour. There is numbness and tingling, first of the mouth and fauces, later becoming general. There is a sense of dryness and of constriction in the throat. Persistent vomiting usually occurs, but is absent in some cases. There is diminished sensibility, with numbness, great muscular feebleness, giddiness, loss of speech, irregularity and failure of the heart's action. Death may result from shock after large doses of the alkaloid, but usually it is by syncope.

The symptoms of poisoning by lead are: "Metallic taste; dryness of the throat; thirst; severe colicky abdominal pains, referred particularly to the umbilical region, and relieved by pressure; pulse very feeble and slow; great prostration; constipation; urine scanty and red; violent cramps; paralysis of the lower extremities; convulsions, and tetanic spasms."

BACTERIOLOGY.

1. To prove that a microorganism is the cause of disease it is essential: (1) That the microorganism be found in the tissues, blood, or secretions of a person or animal sick or dead of the disease; (2) the microorganism must be isolated and cultivated from these same sources; it must also be grown for several generations in artificial culture media; (3) the pure cultures, when thus obtained, must, on inoculation into a healthy and susceptible animal, produce the diseases in question, and (4), the same microorganisms must again be found in the tissues, blood, or secretions of the inoculated animal.

2. The three basic forms of bacteria are: (1) The *coccus*, which is round or oval, and may appear singly, in pairs, in groups of four, in chains, or in bunches. (2) The *bacillus*, which is rod shaped, with the longer sides parallel and the short ends either straight, rounded, or concave. (3) The *spirillum*, which is spiral.

3. Streptococcus erysipelatis; see French's "Practice of Medicine" (1910), page 218; or Osler's "Practice of Medicine" (1909), page 210.

4. *To distinguish the typhoid bacillus from the colon bacillus:* (1) On gelatin plates the colonies of typhoid develop more slowly than those of colon bacillus. (2) The colon bacillus causes fermentation with production of gas in media which contains sugar; the typhoid bacillus does not. (3) The colon bacillus produces a strong acid reaction and coagulates milk within twenty-four to forty-eight hours; the typhoid bacillus does not coagulate milk. (4) In peptone solution the colon bacillus produces indol; the typhoid bacillus does not. (5) The typhoid bacillus gives the Widal reaction with typhoid serum; the colon bacillus does not.

5. The bacillus of tetanus is characterized by its peculiar spore, formed at one end of the bacillus, and giving it the appearance of a pin; it is purely anaërobic, and cannot be developed at all in the presence of oxygen. It generally comes from the soil, and is found in penetrating wounds. It appears in two forms, the spore-bearing form, as described above, and the vegetative form, which is a short bacillus with rounded ends, and which may occur singly or in pairs, or may form long filaments. It grows in gelatin stab cultures in the middle of the medium, and the colonies look something like a fir tree; its growth is slow, and a disagreeable odor is at the same time emitted. In bouillon it grows near the bottom of the tube and produces gases.

PATHOLOGY.

1. See French's "Practice of Medicine" (1910), page 154; or Osler's "Practice of Medicine" (1909), page 170.

2. See French's "Practice of Medicine" (1910), page 840; or Osler's "Practice of Medicine" (1909), page 539.

3. See French's "Practice of Medicine" (1910), pages 911 and 918; or Osler's "Practice of Medicine" (1909), page 692.

4. See French's "Practice of Medicine" (1910), page 1082; or Osler's "Practice of Medicine" (1909), page 887.

5. See Rose and Carless' "Surgery" (1908), page 105; or Da Costa's "Surgery" (1908), page 170.

6. See French's "Practice of Medicine" (1910), pages 35 and 36.

7. See Rose and Carless' "Surgery" (1908), pages 183, etc.; or Da Costa's "Surgery" (1908), pages 296, etc.

8. See Rose and Carless' "Surgery" (1908), page 40; or Da Costa's "Surgery" (1908), page 81.

9. *Arterial hyperemia:* "Excessive stimulation of the vasoconstrictor fibers, active stimulation of the vasodilators, and injury of the vascular muscle fibers all have in the end the same effect of causing active hyperemia, which explains many contradictory drug actions through paralysis by overstimulation. Sudden removal of support may cause active hyperemia in the vessels of various parts, as when a large amount of residual urine is incautiously withdrawn and hemorrhage follows from the vessels which had become accustomed to its pressure. So also the relief of pressure anemia is followed by hyperemia, as when a tight shoe by its removal allows the part to be filled by blood, with consequent growth of the corn which is the joint result of intermittent pressure and blood supply."—(Thayer's *Pathology.*)

10. See French's "Practice of Medicine" (1910), pages 25 and 27; or Rose and Carless' "Surgery" (1908), pages 344 and 347; or Da Costa's "Surgery" (1908), pages 185, etc.

PHYSICAL DIAGNOSIS.

1. See French's "Practice of Medicine" (1910), page 242; or Osler's "Practice of Medicine" (1909), page 16.

2. See French's "Practice of Medicine" (1910), page 518; or Osler's "Practice of Medicine" (1909), page 726.

3. See French's "Practice of Medicine" (1910), page 735; or Osler's "Practice of Medicine" (1909), page 445.

4. See French's "Practice of Medicine" (1910), pages 242, 518, and 520; or Osler's "Practice of Medicine" (1909), pages 16 and 726.

5. See French's "Practice of Medicine" (1910), page 663; or Osler's "Practice of Medicine" (1909), page 599.

6. See French's "Practice of Medicine" (1910), pages 663 and 735; or Osler's "Practice of Medicine" (1909), pages 599 and 445.

7. See French's "Practice of Medicine" (1910), page 254; or Osler's "Practice of Medicine" (1909), page 245.

8. See French's "Practice of Medicine" (1910), page 831.

9. See French's "Practice of Medicine" (1910), page 74; or Osler's "Practice of Medicine" (1909), page 70.

10. The following table is taken from an elaborate one by Thayer:

TYPHOID FEVER.	MALARIAL (REMITTENT) FEVER.
Blood shows no leucocytosis; eosinophiles diminished or absent; serum causes agglomeration of typhoid bacilli; malarial parasites and pigment absent.	Blood shows no leucocytosis; eosinophiles not notably diminished; serum does not cause agglomeration of typhoid bacilli; malarial parasites and pigmented leucocytes present.
Fever uninfluenced by quinine.	Fever disappears under quinine.
Usually epidemic; prevailing commonly in cities.	Is an endemic disease occurring particularly in rural districts; rarely epidemic.
Anemia absent, excepting in later stages.	Anemia more or less marked early in the course.
Characteristic roseola.	No characteristic exanthem; urticaria not uncommon.
Has a fairly characteristic course.	No distinct course.
Urine high-colored; bile absent; Ehrlich's diazo-reaction present during the height of the process.	Urine high-colored; may show a trace of bile; Ehrlich's diazo-reaction rarely present.
Onset gradual and progressive.	Onset generally intermittent.
The temperature does not reach 40° C. (104° F.) before the third or fourth day.	The temperature may arrive at 40° C. (104° F.) within twenty-four hours.
The apathetic expression of the face, the dryness of the tongue, and sordes upon the teeth are well marked and progressive.	The symptoms are not very marked.
Herpes rare.	Herpes common.

OBSTETRICS AND HYGIENE.

1. Parturition is the act of giving birth to a child.

2. See Williams' "Obstetrics" (1909), pages 226, 229 and 292; or Hirst's "Obstetrics" (1909), pages 320 and 341.
3. See Williams' "Obstetrics" (1909), pages 173, 200 and 491; or Hirst's "Obstetrics" (1909), pages 187 and 242.
4. See Williams' "Obstetrics" (1909), page 100; or Hirst's "Obstetrics" (1909), page 204.
5. See Hirst's "Obstetrics" (1909), page 926.
6. Symptoms of death of fetus are: cessation of the signs of pregnancy, the abdomen and uterus are both diminished in size, the fetal heart sounds and movements are absent, there is no pulsation in the cord, the mother's breasts become flaccid and occasionally secrete milk. If the fetus has been dead for some time, crepitus of its cranial bones may be elicited.
7. See Williams' "Obstetrics" (1909), page 289; or Hirst's "Obstetrics" (1909), page 419.
8. See Williams' "Obstetrics" (1909), page 435 and 437; or Hirst's "Obstetrics" (1909), pages 830 and 827.
9. Typhoid fever is transmitted through the food and drink becoming contaminated; flies may aid in this contamination.

Typhoid fever is preventable. All water for drinking or for washing dishes, etc., and milk should be boiled; no ice should be put *in* water or other drink or food; flies should be kept out of the house; all discharges from the sick person must be disinfected; all utensils, dishes, etc., used by the patient must be thoroughly cleansed, and boiled every day; soiled linen must be soaked in a disinfectant solution before being washed; after each attendance on a patient, physicians, nurses, and others should wash their hands in a disinfectant; thorough sterilization of all bedding, etc., must be performed after the disease is over.

10. See French's "Practice of Medicine" (1910), page 798; or Osler's "Practice of Medicine" (1909), page 509.

GYNECOLOGY.

1. *Urethral caruncle* is a small red fleshy growth generally situated on the posterior part of the meatus of the urethra. There are local pain and tenderness, which may be excessive; a burning sensation is experienced on urination; it may bleed. The proper treatment is to excise it or destroy it with the thermocautery.
2. PROLAPSIS UTERI. *Definition:* A condition in which the uterus sinks below its normal level, but does not protrude through the vagina. *Pathology:* "Decrease in the power of uterine support. Distention and eversion of the vagina with decrease in the power of its sphincter and thickening of its epithelium. The uterus is enlarged from impairment of its circulation, its cavity is increased in size, and hyperplasia of its areolar tissue may result. The endometrium becomes thickened, congested, and inflamed. Ectropion may occur. Varicose degeneration of the vessels of the cervix may take place with consequent absorption of its proper tissue; ulceration may also occur. Pelvic congestion from compression of the hypogastric veins. Tension on the broad ligaments may produce obstruction of ureters and hydronephrosis. Occasionally, epithelioma from continued irritation of the cervix. Varicocele of the pampiniform plexus from torsion of the broad ligaments. When cystocele is present, complete evacuation of the bladder cannot be obtained, and the result is dysuria, ardor urinæ and cystitis or retention of urine."

Etiology: Injury at childbirth, lacerated perineum, relaxation and elongation of the ligaments of the uterus, loss of rigidity of the abdominal walls, increase in the weight of the uterus, subinvolution, increased intraabdominal pressure. *Treatment:* "Operative, unless some contraindication to operation exists. In such a case some *mechanic device* should be tried for the support of the uterus. Pessaries are not to be recommended, as their constant use leads to irritation and excoriation of the vaginal walls. Probably the best means for supporting the uterus is by Braun's colpeurynter. This is worn only during the day, and can be introduced by the patient herself every morning. The uterus is replaced and the colpeurynter, well anointed with carbolized vaseline and containing about an ounce of water, is introduced into the vagina. It is then distended with air, thus making an even pressure on the vaginal walls and not causing ulcerations. *Operative treatment* gives the most satisfactory results in prolapse. In slight cases of prolapse repair of the perineum will effect a cure. The severer grades will require, in addition, some operation on the anterior vagina. The best of these is Martin's operation for cystocele. If the cervix is hypertrophied it should be amputated. Three operations—on the perineum, for cystocele, and amputation of the cervix—are required in the usual case of prolapse. In addition, hysterorrhaphy may be advisable, since there can be no prolapse so long as the uterus maintains its normal position of anteflexion. These operations failing, hysterectomy may be performed."
3. See Rose and Carless' "Surgery" (1908), page 1288.
4. *Vicarious menstruation* is the flow of blood from some organ (other than the uterus) recurring at the monthly periods and taking the place of menstruation. It may occur from the hemorrhoidal vessels, the lungs, the skin, under the nails, the mammary glands, ulcerated surfaces, and many other parts.
5. ACUTE PELVIC PERITONITIS. *Symptoms:* Intense and diffuse abdominal pain, tenderness, and distention; vomiting, constipation, elevation of the temperature (103°-104° F.), small, hard, rapid, and wiry pulse (120-140), and increased respiration (30-40) of a painful character are also present. The dorsal decubitus with the legs and thighs drawn up is assumed.
6. Pruritus vulvæ is a condition characterized by intense itching of the external genitals. It may be *caused by*: Parasites; diseases of the vulva, as inflammation, edema, vegetations, congestion, irritating discharges, lack of cleanliness, diabetic urine; it may also be of nervous origin, or idiopathic. *Treatment* consists in removing the cause, if possible; cleanliness, fresh air, tonics, and general attention to hygiene; local applications of solution of bichloride of mercury, 1:2,000; or carbolic acid, 1:100; or lead and opium; dusting powders of bismuth subnitrate, calomel, or zinc oxide are also useful.
7. Possible results of gonorrhea in the female. Cystitis, urethritis, vulvitis, endometritis, salpingitis, septic peritonitis, sterility, condylomata of vulva, abscess of Bartholin's glands.
8. See Williams' "Obstetrics" (1909), page 640; or Hirst's "Obstetrics" (1909), pages 295 and 187.
9. *Amenorrhea* is absence of menstruation during the period of sexual activity.

Dysmenorrhea is painful menstruation.

Menorrhagia is a condition characterized by excessive loss of blood during the menstrual periods.

10. See Williams' "Obstetrics" (1909), page 904; or Hirst's "Obstetrics" (1909), pages 645 and 647.

SURGERY.

1. See Rose and Carless' "Surgery" (1908), pages 82 and 85; or Da Costa's "Surgery (1908), page 124.
2. See Rose and Carless' "Surgery" (1908), pages 83, 85 and 87; or Da Costa's "Surgery" (1908), pages 197 and 199.
3. See Rose and Carless' "Surgery" (1908), page 129; or Da Costa's "Surgery" (1908), page 268.
4. The following contraindications for ether and chloroform are from Hare's *Practical Therapeutics:* "Ether should not be used by inhalation in bronchitis or acute nephritis, because of its irritant properties; in peritonitis or gastritis, because it is apt to induce vomiting; in aneurysm or in the presence of marked vascular atheroma, because it may rupture a blood-vessel by raising arterial pressure; nor in diabetes, lest it produce diabetic coma; and if anemia is present and an examination of the blood shows that the hemoglobin is below 50 per cent. the use of the drug should be avoided if possible.

"*Chloroform* is not to be used in cases of fatty heart or dilatation of the heart, in those with a known idiosyncrasy, nor in the so-called lymphatic persons with overgrowth of lymphoid tissues, as, for example, adenoids. In the latter case it is particularly apt to cause sudden death. In valvular disease of the heart chloroform may be used with caution, although either is preferable. Given a case of valvular disease that must be subjected to operation, the chances are bettered with an anesthetic than without it, as the pain and mental shock are worse for the heart than is the anesthetic."

Nitrous oxide is contraindicated in the presence of vascular degeneration; advanced heart disease; and conditions in which muscular relaxation is required.

6. See Rose and Carless' "Surgery" (1908), page 620; or Da Costa's "Surgery" (1908), page 587.
7.

FRACTURE.	DISLOCATION.
1. Crepitus may be present.	1. Crepitus never present.
2. Preternatural mobility.	2. Rigidity rather than mobility.
3. Easily reduced—but	3. Difficult to reduce—but
4. Deformity more liable to recur after reduction.	4. Deformity less liable to recur after reduction.
5. The head of the bone is in its proper place.	5. The head of the bone is not in its proper place.

FRACTURE.	DISLOCATION.
6. The socket containing the head of the bone is not empty.	6. The socket which should contain the head of the bone is empty.
7. When rotated the bone does not move as one piece.	7. When rotated the bone moves as one piece.

8. See Rose and Carless' "Surgery" (1908), page 521; or Da Costa's "Surgery" (1908), page 505.

9. See Rose and Carless' "Surgery" (1908), page 1316; or Da Costa's "Surgery" (1908), page 1223.

10. Skin, superficial fascia, aponeurosis of external oblique, peritoneum.

BULLETIN OF APPROACHING EXAMINATIONS.

STATE	NAME AND ADDRESS OF SECRETARY	PLACE AND DATE OF NEXT EXAMINATION†	
Alabama*	W. H. Sanders, Montgomery	Montgomery	Jan. 9
Arizona*	Ancil Martin, Phoenix	Phoenix	Jan. 2
Arkansas	F. T. Murphy, Brinkley	Little Rock	Nov. 14
California*	Chas. L. Tisdale, 929 Butler Building, San Francisco	Los Angeles	Dec. 5
Colorado	David A. Strickler, Empire Building, Denver	Denver	Jan. 2
Connecticut*	Chas. A Tuttle, New Haven	New Haven	Nov. 14
Delaware	J. H. Wilson, Dover	Dover	Dec. 12
Dist. of Col'ba	Geo. C. Ober, Washington	Washington	Jan. 11
Florida*	I. D. Fernandez, Jacksonville	Jacksonville	Nov. 7
Georgia	C. T. Nolan, Marietta	Atlanta	
Idaho*	O. J. Allen, Bellevue	Boise	April 2
Illinois	J. A Egan, Springfield	Chicago	
Indiana	W. T. Gott, Crawfordsville	Indianapolis	Jan. 9

Wyoming	A. B. Tonkin, Riverton	Riverton	Jan. 9

*No reciprocity recognized by these States.

†Applicants should in every case write to the secretary for all the details regarding the examination in any particular State.

Wisconsin.—At a meeting of the Board held at Madison, July 11-13, 1911, it was decided that hereafter the board will demand documentary evidence of preliminary education in the form either of a high school diploma or a certificate signed by the proper examiner for the State from which the applicant comes showing that he has an equivalent education. Furthermore, the board will require that hereafter all conditions must be made up before the student is admitted to the junior year. The board also resolved that in all examinations hereafter practical tests will be required in physical diagnosis, chemical and microscopic uranalysis, bacteriology, pathology, histology, and practical anatomy.

Montana.—Twenty-three out of a class of thirty-six who took the recent examination before the Montana State Board of Medical Examiners were successful.

Massachusetts.—Complaint is made by Massachusetts physicians that the medical registration law in that State is not sufficiently stringent in that it does not specify that applicants shall be graduates of a medical school.

Medical Items

Experimental Researches on the Etiology of Estival Fever.—Melchiorre Napolitani and Aldo Tedeschi have made researches into the etiology of the so-called estival fever, and present their conclusions. The clinical characteristics as seen among military men are nervous phenomena, such as headache, chills, delirium, high temperature and severe depression. Sometimes the fever comes without prodromal symptoms. The author has traced the infection to the *Phlebotomus pappatasii*, which he believes carries the causative organism in this disease. Only the female sucks blood, since the male is not provided with suctorial organs. The larvæ live in dark and damp places, among filth; the nymphæ are found in similar places. The adults live by preference in houses. Inoculation experiments were made in animals and in man, and succeeded in producing the disease. The author's conclusions are that the cause of estival fever is a filterable virus; the transmitting agent is the *Phlebotomus pappatasii;* the period of incubation is 4-5 days; in the pappatasii the virus remains active for as long as ten days; to contract the disease it is necessary to be punctured by the pappatasii.—*Giornale de Medicina Militare.*

Health Reports.—The following cases of and deaths from smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine Hospital Service, during the week ended October 27, 1911:

BLOOD PRESSURE IN PROGNOSIS.*

BY HENRY WIREMAN COOK, M.D.,

MINNEAPOLIS, MINN.

THE true estimate of any apparent advance in knowledge must lie somewhere between the optimism of the enthusiast and the pessimism of the reactionist. Obviously the discussion of a settled question can be of little value. Yet one must remember in attempting to discuss a question which is still *sub judice* that our conclusion must occupy an indefinite place in relation to the final consensus of opinion. It will show the errors of the enthusiast or the reactionist reflected from our individual mental attitude. Our conclusion should be drawn from a knowledge of the theory of the subject and the study of the individual experiences and collaborated statistics which bear upon it. In the absence of positive statistical evidence, the best single guide to the practical value of a new method, if a sufficient interval has elapsed since its introduction, is to determine whether it is receiving increasing indorsement from qualified authorities, in spite of the objections of reactionists, or whether it is being gradually dropped or neglected, in spite of the praise of enthusiasts.

If it is permissible to anticipate the general conclusion of this paper, it may be stated here that such mass evidence seems to indicate that the instrumental estimation of blood pressure has become a permanent clinical method, and that its application to life insurance examinations is trending toward general acceptance.

Although von Basch constructed an instrument which gave approximate measurements of blood pressure as early as 1876, modified by Potain in 1889, it was not until 1896 that an instrument was devised which permitted a practical and accurate estimation of arterial pressure. At about the same time, 1896, Riva Rocci, working in Italy, and Hill in England, devised a simple and practical instrument, the former for the measurement of systolic pressure, the latter for diastolic pressure. The air system, the constricting band, and the monometer of the Riva Rocci instrument, are familiar to all, and appear more or less modified as the essentials in all sphygmomanometers now in general use. Numerous foreign articles on clinical methods of measuring blood pressure had appeared in 1901, when Howell and Brush published the first American article in the *Boston Medical and Surgical Journal*. The subject then in this country is but ten years old, and has received general attention only during the past five or six years. The wide interest is, however, indicated by the appended bibliography, which is limited to literature appearing within the past eighteen months, and which shows a total of 140 articles.

The proper use of the Riva Rocci sphygmomanometer in obtaining systolic pressures is now well known. In addition to the usual methods of palpation there is a more recent method of auscultatory estimation by listening for variations in sound with a stethoscope applied over the brachial below the constricting band. Another method is a visual estimation, by the use of Dr. V. Pachon's sphygmo-oscillometer, the disappearance and reappearance of the pulse wave being indicated by a needle. No very definite improvement has been demonstrated for these methods, and certainly at this time they need not concern us here. In the use of a sphygmomanometer we should be sure that the constricting band is at last 10 c.m. wide; that it is applied snugly well above the elbow joint; and, when a mercury manometer is not employed, that the device reads correctly—the mercury column being used occasionally as a standard. In determining the systolic pressure it is preferable to take a figure half way between the point of disappearance of the pulse and the point of reappearance, and several consecutive observations should be made to establish a mean.

Following the work of Erlanger, it has been demonstrated that in certain cases a knowledge of diastolic pressures and pulse pressures is of distinct clinical value; for example, the work of Wiggers on pulse pressure during hemorrhage, or Sheldon's interpretation of diastolic pressures and pulse pressures in certain cardiac conditions. But the methods of obtaining diastolic pressure are too technical at the present time, and the interpretation too vague to make it of positive value in connection with the topic under consideration. At the present time all well-equipped hospitals have sphygmomanometers in daily use in the wards: nor is this use confined to the medical wards; in fact, the instrumental measurement of pulse tension was probably used in this country as early by Harvey Cushing in the surgical wards of Johns Hopkins Hospital as by Theodore Janeway in the medical wards of the City Hospital, New York. It is seen in children's wards, as a guide to stimulation and other treatment; in obstetrical wards, in diagnosis and treatment of toxemias; in surgical wards, in the preparation of certain dangerous cases of high tension, myocarditis, or nephritis, and in following their condition in the operating room. The oculist and the aurist are finding blood-pressure measurements of increasing value, and tuberculosis sanatoria are modifying their prognoses and treatment according to the indications of this sign. I venture to say that no case history would to-day be considered complete by a competent internist without a record of pulse tension.

I shall assume, then, without further argument, that blood pressure is an important clinical sign, and that the instrumental measurement of this sign, thus permitting of its being recorded and used compara-

*Read at a meeting of the Medical Section of the American Life Convention, held in Pittsburgh, Pa., September 20, 1911.

tively as well as absolutely, is a signal advance in medical practice, deserving to rank with the advance in estimation of temperature over tactile impression or a blood count over visual estimates. The acknowledgment of this clinical usage is, however, no indication that it is of equal value, or in fact of any value to us in insurance examinations. A leucocyte count over 15,000 would make us hesitate to approve a risk, yet this requirement will never appear in our blanks. If we had the benefit of a tuberculin test in all applicants under 45, the relative position of tuberculosis in our mortality statistics would probably be changed. If we could give a hypodermic of phenolsulphonephthalein to all applicants over 45 and have accurate measurement of the amount excreted in an hour, we would undoubtedly have fewer recent entrants with impaired renal function. Notation of a coated tongue appears in clinical histories, but is omitted from an insurance blank. Thus a sign may be of clinical value and yet be too technical for the average examiner, too annoying for the applicant, or as in the case of a coated tongue, might be so often associated with trivial causes as to be only a source of confusion.

The medical examination is at the present time a lengthy affair, and we should hesitate before making it more complicated. In the consideration of the applicability of an additional prognostic sign to the insurance examination, we should weigh very seriously whether it is of sufficient importance to justify the disadvantages. In addition to authoritative clinical endorsement:

It should be within the ability of the possible, not the ideal, examiner.

It should permit conclusions as to prognosis not possible from the physical examination already required.

It should not entail hardship nor undue annoyance on the applicant.

Further, whether its bearing was on those diseases and conditions which played a large part, or on those which played a small part in insurance mortality, would tend to determine its scope of usefulness.

Finally, in order to maintain a permanent place in this field, statistical evidence should show that action guided by the use of data thus obtained permitted a more accurate selection.

One of the most seriously urged objections to the use of the sphygmomanometer has been that the average physician in the small town is not equipped with an instrument. This condition would, of course, remain only until such time as this sign was required by a sufficient number of companies. Insurance appointments aggregating $10 to $400 a month to different examiners, are too valuable for physicians to permit the expense of $6.50 to $10 to stand in the way of satisfactory service. If insurance companies want blood pressure readings and require them, examiners will equip themselves—of that we may be assured. Several large companies have required blood pressure in certain cases since 1906. One of them has tabulated the results of 4,000 observations. At the present time over one hundred companies are requiring this sign. One company in Texas, within a year following a circular letter from the home office on the subject, found that 200, or 50 per cent. of their Texas examiners were equipped to give blood pressure readings when requested. Equally accurate data from other States would probably give as good, if not a better, showing. If the present rate of increase in this direction continues, it is safe to say that within five years a blood pressure reading can be obtained in practically every town where there is a regular physician capable of making an ordinary uranalysis.

I think it is worth more than passing comment that insurance companies should thus be compelled to point out to the physicians of the country the necessity for properly equipping themselves. It might be interpreted as an emphasis of the well-known inferiority of the physician turned out by the majority of medical schools of this country, and indicates the highly beneficial influence that insurance companies are exerting on medical standards. Physicians who can practice successfully without materials for a uranalysis or a blood pressure instrument, will find it difficult to hold insurance appointments; and conversely, patients are learning that an examiner who is preferred by Old Line companies is the safest man to trust as a physician.

Janeway is always conservative in his statements. In a recent article under the title, "When should the general practitioner measure blood pressure?" he deems it absolutely necessary for competent work, and ranks it of first importance in every careful examination of the cardiovascular system, specifying under separate headings, the first examination of every new patient, and every examination made for the purpose of certifying to the existence of a state of health—including applicants for life insurance, recruits for the army, navy, police and fire departments, etc. He further mentions obstetrical work, diagnosis of abdominal pain, etc.

Granted that a physician has an instrument for measuring blood pressure, some hold the opinion that only an expert can use the instrument and give reliable readings. This contention I cannot understand, and believe it must arise from lack of any practical experience on the subject. I admit freely that the average physician is not properly trained or educated, but I cannot believe that he is incapable of determining whether or not the pulse is beating in the radial. This is the only required attainment. I have had occasion personally to instruct students in three different medical schools in as many different States during the past ten years, and I have yet to find one who could not after five minutes' practice give a proper reading. Furthermore, in the Johns Hopkins Hospital, in the Memorial Hospital, Richmond, and Thomas Wilson Sanitarium, Maryland, I have had nurses accurately follow the blood pressure, keeping a chart record from day to day, controlled by observations of the medical attendant.

When blood pressure observations are obtained from many examiners, undoubtedly there would be a certain proportion of no value; a figure would be given without the trouble of using the instrument, or only the form would be gone through without a sincere effort to obtain an accurate reading. This, however, we have learned to expect in regard to every question in our blanks. What percentage of examiners never examine the urine; how many never remove the clothing over heart and lungs; as a matter of fact, do 90 per cent. of the examiners of any company find albumen if it is present only in minute traces? We are replacing poor examiners with better; we believe that medical graduates are better trained each year; we are continually attempting to educate our examiners and control their work. In spite of the poor work obtained from many, we continue to ask for reports on heart, lungs, and urine. It would appear that the incompetence of American physi-

cians is one of the strongest arguments *for* and not *against* requirement of blood pressure estimation, because it is the simplest and easiest part of the physical examination, next to counting the pulse and taking weight and measurements. A hundred examiners could give us a reliable blood pressure reading where *one* could detect cardiac hypertrophy, or an accentuated second aortic in a stout person, or a minute trace of albumen in a chronic interstitial nephritic.

A contrary opinion has been expressed by several prominent medical directors, to the effect that examiners who could take a blood pressure reading could detect an abnormal variation in tension either by palpation or by associated signs. In other words, that the ordinary physical examination as now required would reveal any condition that would be indicated by an instrumental estimation of blood-pressure. It is difficult to understand this opinion because clinical evidence is so overwhelming against it. I have personally heard Osler, Barker, Thayer, Janeway, Greene, and other clinical teachers of eminence deny their ability to estimate tension accurately by palpation. Certainly no one would contend that the degree of cardiac hypertrophy as obtained by percussion or the relative intensity of the aortic second as heard by auscultation could be used as an accurate indication of the degree of tension. I know of only one clinician who still maintains that he can estimate tension accurately by palpation: Hoover of Cleveland says that by palpating the femoral artery at Poupart's ligament he can very accurately estimate the tension, rarely, as he says, having a disparity of more than 20 mm. in pressures between 150 mm. and 250 mm. He adds: "I readily admit the impossibility of making an accurate estimate of blood-pressure from the radial or even the brachial." However interesting Hoover's ability to ordinarily measure the tension in the femoral within 20 mm. may be, it does not affect the present discussion. Twenty mm. is too wide a variation for practical purposes. The difference, for instance, between 145 mm. and 165 mm. cannot be neglected, nor is the femoral accessible in an insurance examination. Clinicians are practically unanimously of the opinion that instrumental estimation of blood-pressure cannot be replaced, where accuracy is desired, by any other data.

If a blood-pressure estimation entailed any pain or caused unreasonable annoyance to an applicant, it would be impractical, no matter how valuable might be its evidence, but no such objection could be made in this instance. An applicant should certainly have removed his coat, and unless he has on a thick flannel undershirt, the sleeve can be rolled up sufficiently to permit adjustment of the band. In the case of thick underwear it is not unreasonable to request removal of the sleeve. With a little practice, an observation requires not more than a minute after the band has been adjusted. I have never had an applicant object, nor ever heard of one objecting to the instrument, and usually I have found them interested and anxious to know the result of the observation.

If our examiners can give us accurately and without serious objection from the applicant the reading of a sphygmomanometer when the pulse returns at the wrist after obliteration, does such a figure give us any reliable information as to the average pulse tension for that individual? This question might be assumed to be answered by the present scope of clinical usage. As it has been urged especially in connection with life insurance examinations, it may properly be answered here. The width of the cuff, the thickness and elasticity of the artery, the size of the arm, the time of day, food, drugs, the mental condition, the age—each of these factors has its influence on the blood-pressure; but I think it can be shown that this variation is either negligible or possible of control. Medicine is probably the least exact of all sciences. I know of no single sign or symptom that permits a positive conclusion; râles, fever, heart murmurs, tachycardia, albuminuria, may mean much or nothing. In my experience an abnormal variation in blood pressure has been more constantly associated with organic disease than any of the above signs. The employment of too narrow an arm piece has led to errors, but so far as I know, following the work of v. Recklinghausen, all instruments indicate recognition of this factor, and are supplied with an arm piece at least 10 cm. in width (10 to 12 cm. is probably better), so that this source of error is eliminated. The normal artery was early shown by v. Basch to be a negligible factor, as he found experimentally that 1 mm. of pressure was sufficient to close the lumen. The recent extensive experimental work of Janeway and Park shows that "with normal arteries and a normal range of blood-pressure the arterial wall is a practically negligible factor; that atheroma, even of considerable degree, is without appreciable effect on compressibility; and finally, if a wide arm piece and the return of the first fully developed pulse wave be taken as an index, even advanced arterial thickening and calcification do not introduce an error of any importance."

There is a factor of error in attempting to estimate the actual blood-pressure, which has been urged by Russell, and which may be operative in certain cases, and which has received but little attention. The work of Janeway and Park confirms the contention that tonic contraction of an artery may materially decrease its compressibility, possibly as much as 30 mm. Hg. Sufficient work, however, clinical and experimental, has not been done to show in what conditions, if any, this hypertonus is present, nor has it been shown that this vasoconstriction of the larger arteries would not be associated with an actual increase in tension. Arteries are not normally in this state of extreme contraction, and so for our purpose, unless it could be definitely shown to be due to temporary nervous influences, the high reading, though not the exact systolic blood-pressure, would still indicate an impairment. We must think of some serious nervous contraction, marked toxemia of some kind, or altered internal secretion (adrenal?). Furthermore, this factor must be rare, as any such marked variation from the normal is most unusual in the absence of disease, in all recorded observations.

The size of the arm has been shown by numerous observers, especially Hensen and Janeway, to be a negligible factor, provided a wide arm piece is used. The pressure exerted by the band is transmitted through the semifluid tissues as through a liquid without appreciable loss. As Janeway points out, if the size of the arm were an important factor, low pressures would be impossible in large arms—and in his experience and that of other observers this is not true. I have at this time under observation a man weighing 240 pounds, fifty years old, in excellent health, whose blood-pressure is constant between 110 mm. and 120 mm. Several years ago

in testing the blood-pressure in a group of students, we were all surprised to find that the lowest reading was in the stoutest of the group. The band could with difficulty be made to encircle the arm. Undoubtedly, high blood-pressures are more common in stout men, and a group of this class, especially over forty-five, would show a higher blood-pressure than men of normal weight, but our clinical knowledge of the incidence of arteriosclerosis, cardiac hypertrophy, and dilatation, and nephritis, in overweights, confirmed by insurance statistics, would anticipate such a finding.

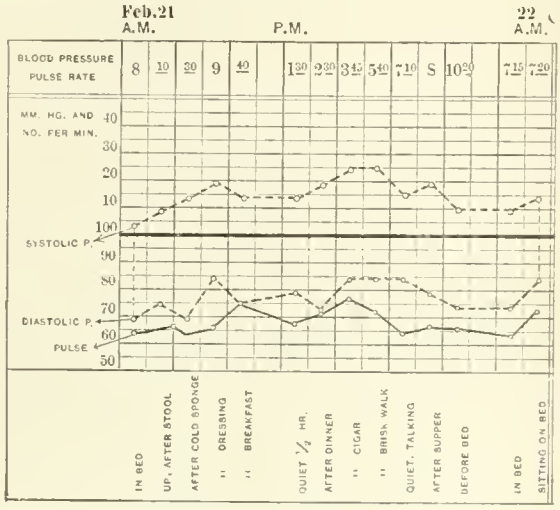

Fig. 1.—Diurnal blood-pressure chart of a healthy man. (From Janeway's "Study of Blood-pressure." New York, D. Appleton & Co.)

There are distinct variations in blood-pressure, to correspond to the waking and sleeping states, averaging from 10 mm. to 20 mm. lower during sleep. Janeway's chart shows graphically the diurnal blood-pressure chart of a healthy man. The variation, however, from 8:30 A. M. to 8:30 P. M. is within 10 mm. Observers vary as to the effect of meals, some showing a fall of 5 mm. to 10 mm., others a rise of 5 mm. to 10 mm. The difference of opinion and the variation being within normal limits would indicate that the effect, if any, was not constant or important. A change of posture shows a variation within the same limits, 5 mm. to 10 mm.

Of drugs, the nitrites used in normal individuals and some cases of high tension cause a marked fall in blood-pressure. Adrenalin intravenously will produce a marked rise in blood-pressure. Strychnine, caffeine, digitalis, may or may not produce a slight rise. Alcohol in moderation produces a slight fall in blood-pressure, but not enough to affect the normal limits. Tobacco in excess, especially when one is unaccustomed to its use, causes a temporary rise of from 10 mm. to 20 mm. A dose of nitrite in a case of high tension just before examination might seriously mislead. Otherwise the effect of drugs need not be considered here.

A rise of 10 mm. to 20 mm. is said to be produced by muscular or mental exertion or moderate excitement. Extreme fright or anxiety would probably cause a rise above normal limits, but these are factors easily controlled in an insurance examination. In the experience of practically all observers, a rise in pulse *rate* above the accepted normal maximum of 90 is far more frequent under the nervousness of a medical examination than a rise in blood-pressure above 5 mm. or 10 mm. In my personal experience during the past ten years in taking blood-pressure, I do not remember a single instance when nervousness or excitement at examination produced an appreciable error.

Age, after childhood, is constantly assuming a less and less important place as a factor in normal blood-pressure variations. In early observations high blood-pressures at older ages were found of so much greater relative frequency that practically all observers were misled into the belief that much higher blood-pressures were normal at the older ages than is actually the case. This partly arose from the use of a narrow arm piece which unduly emphasized any increase, but probably in most part the mistake was due to the fact that cardiovascular and renal changes are so much more common after forty-five. Later and more accurate observations, however, showed that there is very little normal increase in blood-pressure before sixty years of age, and that when a marked hypertension is present it is associated with a distinct abnormality of tissue or function. Authoritative data on this point are most convincing.

In over two hundred consecutive blood-pressure observations Janeway saw 145 mm. Hg exceeded only once or twice, except where cause for hypertension existed. In routine examinations of many hundreds of cases he never saw a pressure above 160 mm. in a normal person—seldom one above 140 mm. (wide arm piece). He regards with suspicion any pressure over 145 mm. His later statement, March, 1911, is: "A blood-pressure reading of more than 145 mm. before middle life, or of more than 160 m.m. after, must be considered abnormal." Barach's recent study of ninety observations on males free from sign or symptom of disease found for all ages 110 mm. to 120 mm. the medium normal, and, taking this in conjunction with his observations on patients during four years, he concludes that a range from the medium normal of 20 mm. should be maximum and minimum normal. He further states definitely that figures beyond that are invariably found associated with something abnormal.

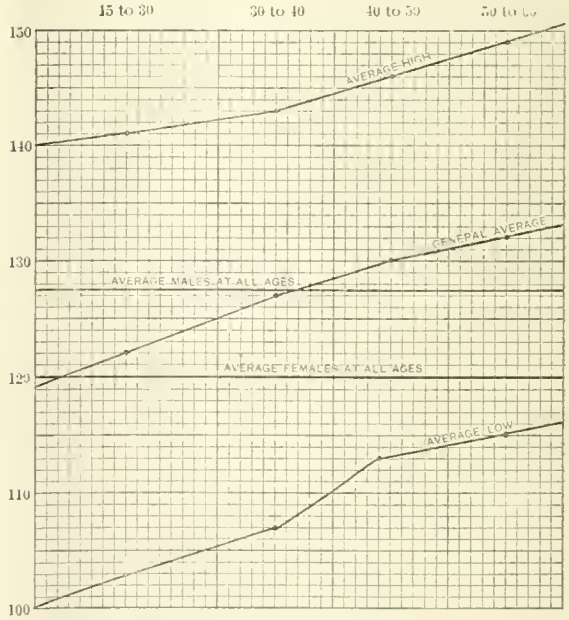

Fig. 2.—Chart of one thousand cases, from "The Normal Variation of the Systolic Blood Pressure," by H. P. Woley, M.D., Journal of American Medical Association, July 9, 1910.

Woley, after observations on 1,000 cases, believes that a blood-pressure of 160 mm. or over is path-

ological. Hayaski, after observing fifty-eight men below sixty, found an average pressure of 132 mm. Doleschal, in one hundred persons, found an average of 120 mm. Thayer, in 276 healthy individuals arranged by decades, records the following: (5 cm. arm piece—above 140 mm. at least 20 mm. should be deducted to interpret in terms of wide arm piece.)

37	cases,	1-10 years	..... 104.6	mm. Hg.
87	"	10-20 "	..... 128.7	"
89	"	20-30 "	..... 136.9	"
37	"	30-40 "	..... 140.8	"
20	"	40-50 "	..... 142.2	"
5	"	50-60 "	..... 154.8	"
1	"	60-70 "	..... 180.	"

Numerous observations on aged persons even with marked arteriosclerosis have shown normal readings. I have under observation a specific example—an old lady eighty-five years of age, in excellent health, whose blood-pressure for five years has not been above 135 mm. Individual cases are sometimes interesting, though dangerous for purpose of generalization. My company accepted without question in 1907 a man fifty years of age, with a blood-pressure of 140 mm., examined and recommended by a competent physician in a large city. Eighteen months later the claim was paid, after the second attack of angina pectoris. Babcock, in discussing a case of myocarditis, considered a blood-pressure of 138 mm. as highly significant, even in a man of fifty-three. In Bachman's list of eighty-five cases six were over fifty years of age, and the highest pressure of the six was 135 mm., in a laborer sixty-two years of age. A tailor sixty years of age showed a pressure of 105 mm. Starling, a London obstetrician, who has for five years been taking blood-pressure in all pregnant women under his care, states: "Any rise above 125 mm. would make me suspect that the pregnancy was not quite normal, and would put me on the lookout for some degree of toxemia." Sahli gives as the high limit of health 135 mm. Faught gives a convenient rule for estimating the normal blood-pressure at different ages, which coincides with the experience of most observers. Taking 120 mm. as the normal at age twenty, he would add ½ mm. for each additional year: thus at age forty, 130 mm., age fifty, 135 mm., age sixty, 140 mm. In June, 1904, the author gave 120 mm. to 130 mm. as normal limits before thirty years of age; 125 to 140 mm. after thirty years of age; over 150 mm., the risk was questionable; over 180 mm., bad.

The tendency, then, has been to restrict the limits of normal variation. As Janeway is the pioneer and highest authority on this subject in the United States, and as his early prophecies have been largely fulfilled, and as his most recent (1911) revised conclusions coincide with those of most observers, it seems proper to accept his doctrine that over 145 mm. before middle life, and over 160 mm. after middle life, must be considered abnormal. As the average normal pressures for these two periods are 120 mm. and 130 mm. respectively, it would seem conservative for the present to consider a blood-pressure between 140 mm. and 160 mm. a definite impairment. I believe that further study will lower this upper limit of 160 mm. by about 10 mm., and that Lauder Brunton's figures will be accepted—115 mm. to 135 mm. or 140 mm. for men in middle life, and that above 150 mm. is an abnormal blood-pressure. The lower limits of normal blood-pressure have received less attention. Infants have a pressure of 90 mm. or slightly under. The normal adult, however, rarely shows a pressure under 105 mm. Lauder Brunton considered under 100 mm. abnormally low. Reitter considers 100 mm. or under abnormal. Hensen's lowest figure in fifty-five individuals was 105 mm. Janeway has put 90 mm. in females and 100 mm. in males as the usual low normal limit. Most observers agree that a pressure under 105 mm. is rare in the normal adult.

In considering blood-pressure as an insurance requirement, it is of particular interest to determine in what condition this sign is of diagnostic or prognostic value, and whether these conditions are important factors in life insurance mortality. Excluding accidents, we might roughly divide the main factors in insurance mortality as well as general mortality into two main groups.

First. Cardiovascular-renal disease, divided into two groups: (a) When cardiovascular-renal disease is the immediate cause of death, *eg.* myocarditis, apoplexy, arteriosclerosis, uremia. (b) Where cardiovascular-renal disease is the primary factor, but a terminal infection—pneumonia, erysipelas, tuberculosis, septicemia—closes the clinical picture. *Second.* Primary infectious diseases, determined by the accident of exposure, the individual resistance, and the virulence of the infection.

The first group, the cardiovascular-renal group, is steadily becoming a relatively and absolutely larger factor, as the danger from the second—infectious—group becomes less. Public sanitation has already removed several diseases, very fatal during the past few decades, from our mortality statistics, and it is not too optimistic to expect that in the coming decades the mortality from typhoid, tuberculosis, and pneumonia, will be still further lowered. The Mutual Life statistics of deaths from 1843 to 1898 show about 30 per cent. due directly to cardiovascular-renal disease. When we consider the part that this factor plays as the primary cause in pneumonia, bronchitis, pulmonary edema, etc. (72 per cent. of the deaths from respiratory diseases were over forty-five years of age), to ascribe one-half of all deaths directly or indirectly to this group would probably not be an overestimate. The census report for 1908 gives about 25 per cent. of total deaths due directly to cardiovascular-renal disease, and this total of course includes the large mortality in infancy and childhood. Clinical evidence proves unequivocally that an increase in tension accompanies or antedates a large proportion of diseases of the cardiovascular and renal systems. An increase in tension produces arteriosclerosis, causes rupture of a diseased artery, apoplexy; overtaxes the heart, myocarditis; accompanies or in some cases apparently causes renal insufficiency, nephritis.

The statement and prophecy of George Dock in 1904, in this country, has been substantiated. In speaking of the relation of arteriosclerosis to nephritis, he said: "It is doubtless true that in many cases the arterial disease causes the renal disease, and the recognition of the earliest stages of arteriosclerosis is only beginning to assume a practical character. By the use of instruments for measuring blood-pressure and by the more careful study of symptoms and physical signs, it will be possible to put the subject on a more definite basis than at present. . . . The importance of hypertension in causing vascular disease is now well recognized." In England, Clifford Allbutt and Lauder Brunton have been preaching the same doctrine for several

decades. The recent clinical deduction of Reed that continued high blood-pressure in a person under forty, or in any except the very old, would alone warrant the diagnosis of either existing or threatened presenile arteriosclerosis is in accordance with the inference of Thayer and Brush in 1904, after a critical study of 3,894 cases at Johns Hopkins Hospital. Their conclusion was as follows: "It seems to us there can be small doubt that the main etiological factor in the development of the hyperplastic thickening of the intima, which constitutes so important an element of arteriosclerosis, is overstrain of the vascular walls, continued or intermittent high tension, whatever its ultimate cause may be."

In quoting authorities on blood-pressure, first position should be given to Sir Lauder Brunton. His own words in opening an address before the British Medical Association in 1908 are most interesting in any study of blood-pressure: "The measurement of blood-pressure in man is a subject in which I have taken a great interest for more than forty years, partly on its own account and partly because I have been fortunate enough to reckon among my personal friends many of the pioneers of this kind of research; Ludwig, Marey, von Basch, Burdon-Sanderson, Gamgee, Kronecker, Mosso, and Oliver." We have the following from this authority: "It seems to be proved by experiment that high tension *per se* will lead to the production of arteriosclerosis and atheroma, and therefore it is of the utmost importance to ascertain the tension of patients in middle life." The experience of Hare (*Journal of the American Medical Association,* October 30, 1909, p. 1507) is particularly instructive as to the value of blood-pressure determinations in insurance work. He holds that arteriosclerosis of the calcareous type is mostly found in the laboring class; the sclerosis resulting from arterial spasm and consequent high tension, usually in the well-to-do or upper class. As the latter are our applicants for Ordinary insurance, especially for the larger policies, his conclusion is pertinent: "The recognition of the underlying vascular state is of the utmost importance in prognosis." A recent editorial in the *Journal of the American Medical Association,* October 1, 1910, discussing Elliott's article, voices the present sentiment: "Increased blood tension, which is now early recognized and actually measured, is the forerunner of all that may happen to a well man. . . . Whatever the cause (of high tension), the etiological factor must be removed or the condition will sooner or later cause cardiovascular-renal disease with its various serious sequelæ."

The report, in March of the present year, of Peter on high tension in eye diseases is most instructive: "High Tension in Eye Diseases" (*Pennsylvania Medical Journal,* March, 1911).

	mm. Hg.
Average pressure in 29 cases of retinitis	165
Average pressure in 59 cases of neuroretinitis	185
Average pressure in 3 cases of albuminuric retinitis	190
Average pressure in 6 cases of hemorrhagic retinitis	205
Average pressure in 3 cases of papillitis	225

The association of high tension and Bright's disease is too well known to require emphasis. The cause of this hypertension is still only vaguely understood. Whether the recent work of Bittorf of Breslau, tending to prove that mechanical obstruction in small branches of the renal artery is cause of high tension; whether Kantenberg's work (*Deutsche medizinische Wochenschrift,* March 25, 1910), showing that this high tension is the result of a toxemia following upon kidney changes; or Loeb's theory of compensatory reflex vasoconstriction will be confirmed; whether adrenal hypertrophy, altered renal secretion, raises the systemic pressure; whether reflex vasoconstrictor impulses from sclerosed aorta and large vessels; or, finally, whether retained waste products or autolysins, possibly nephrolysins, are specific or contributing causes of this symptom can only at present be surmised.

The exact relation of high tension to nephritis, arteriosclerosis, and myocarditis is being extensively studied clinically and experimentally. We can content ourselves with the established fact that hypertension is a sign of preeminent importance in any condition associated with cardiovascular and renal changes, and that before the stage of myocardial incompetence is reached the degree of hypertension is a fair measure of the danger of the condition. In the later stages of these diseases, if the kidneys and arteries endure longer than the myocardium, and if a terminal infection does not interfere, the blood-pressure will gradually fall as the heart muscle fails; so that a man dying of nephritis after ten years of high tension may show a normal blood-pressure. These late conditions should, however, not offer serious difficulties. It is in the early cases, so constantly overlooked by the average examiner, that we need additional diagnostic aids, and it is here that blood-pressure observations will prove invaluable.

If, in addition to giving us accurate information in the large group of cardiovascular-renal diseases associated with high tension, blood-pressure observations could assist us in the exclusion of applicants susceptible to infectious diseases, tuberculosis being the most important, its value and scope would be materially enlarged. There are at present sufficient clinical data to justify the belief that this can be expected in certain cases. Recent clinical work, notably that by Emerson, appearing in the *Archives of Internal Medicine,* April, 1911, and Pottinger, *Archives of Internal Medicine,* October, 1909, shows that relative low pressures are constantly found in tuberculosis, unless some complicating cause of hypertension be present. Lowsley shows low tension in conditions of physical exhaustion; Munzer in cachexia, exophthalmic goiter, and Addison's disease; Sizary in tuberculosis. Thompson and Pearce and Eisenberg in experimental work show effect of certain toxins, for example, peptone, in production of low pressures. Edgecombe finds hypotension in subjects with poor circulation, cold hands and feet, liable to chilblains, neurasthenics, weak heart. Dr. Barker has stated that he has come unconsciously to think of tuberculosis as a probability when hypotension is present.

The experience of Lauder Brunton in a single case and his general opinion are pertinent here. In 1909 he wrote: "About three years ago I met some of my old students at Bloemfontein and gave them a demonstration on blood-pressure. One of the medical men present was the picture of health, but we found his pressure to be only 100 mm. There was no apparent cause for this, and it was simply put down as a personal peculiarity. About a year and a half afterwards I met him at King Edward VII Sanatorium at Midhurst, and he told me that about two months after I had taken his blood-pressure he developed symptoms of phthisis, and had

come home in order to undergo a cure at the sanatorium. I have not sufficient data to justify a generalization, but the coincidence in this case struck me as very remarkable, and I think it may be well to direct attention to the abnormally low blood-pressure as a possible premonitory symptom of phthisis. The blood-pressure is apt to fall much below the normal in cases of general debility from overwork, underfeeding, and especially from acute diseases."

Several paragraphs from Emerson's summary are sufficiently instructive to justify full quotation: "Hypotension or subnormal blood-pressure is universally found in advanced pulmonary tuberculosis, in which condition emaciation may play a part in its causation. Hypotension is found in almost all cases of moderately advanced tuberculosis, or in early cases in which the toxemia is marked, except when arteriosclerosis, the so-called arthritis or gouty diathesis, chronic nephritis, or diabetes complicate the tuberculosis and bring about a normal pressure or a hypertension. Hypotension has been found by so many observers in early, doubtful, or suspected cases with or before physical signs of the disease in the lungs, and is considered by competent clinicians so useful a differential sign between various conditions and tuberculosis, that it should be sought for as carefully as it is the custom at present to search for pulmonary signs. Hypotension when found persistently in individuals or families or classes living under certain unhygienic conditions should put us on our guard against at least a predisposition to tuberculosis. Most unhygienic conditions, overwork, undernourishment, and insufficient air are of themselves causes of a diminished resistance, and it seems likely that a failure of normal cardiovascular response to exercise or change of position may be found to indicate this stage of susceptibility, especially to tuberculous infection. Hypotension, when it is present in tuberculosis, increases with an extension of the process. Recovery from hypotension accompanies arrest or improvement. Return to normal pressure is commonly found in those who are cured. Continuation of hypotension seems never to accompany improvement. Prognosis can as safely be based on the alteration in the blood-pressure as on changes in the pulse or temperature."

We can then, I think, definitely state that a pressure in an adult under 105 mm. warrants further investigation; under 100 mm. should make the case very doubtful. I think knowledge of the blood-pressure in underweights, in cases with a family history of tuberculosis, history of exposure to infection, or suspicious personal history, will prove a valuable additional diagnostic and prognostic sign.

The last word has not been spoken in regard to the value of any insurance data until there has been sufficient experience to permit a determination of actual results. At least two large companies have collected data which appear to show conclusively that medical selection will be greatly improved, at least in certain cases, by a recognition of the blood-pressure. Dr. Fisher of the Northwestern Mutual has shown in a recent paper delivered before the Medical Directors' Association that their mortality in rejected cases where the blood-pressure was over 150 mm. had been four times greater than the general average of the company covering the same period.

The reports received from one hundred and fifty companies in answer to a series of questions* are tabulated as follows: Replies were received from 150 companies. Forty-six companies do not request blood-pressure readings; 6 give no opinion; 7 consider it of no practical value; 33 consider it of value, but unobtainable. One hundred and four companies request blood pressure readings; 6, in all cases; 31, in special cases only; 67, when indicated by amount or age; 4, by amount only, $5,000, $10,000, $25,000; 31, by age only, (1—25), (2—35), (12—40), (7—45), (9—50), 32 by both amount and age, as follows:

No. of Cos.	Amounts.	No. of Cos.	Age (over)
2	$2,000	1	30
1	2,500	1	35
2	3,000	1	38
11	5,000	14	40
1	7,500	8	45
10	10,000	7	50
1	15,000		
4	20,000		

Twenty-six companies have question as to blood pressure in blank.

Of the companies from which replies were received, fifty-eight have over ten million insurance in force. Of these fifty-eight companies having ten million in force, fifty-one request blood-pressure readings; only seven companies, or 12 per cent. do not. Of the one hundred and fifty replies received, we note that one hundred and four companies, or 70 per cent., use blood-pressure at the present time, more or less. This is interesting as compared with the results of a similar investigation by Faught two years ago. In thirty-two replies which he received there were no companies that required blood-pressure in all examinations; twenty-two companies required it in certain cases; ten companies did not employ it at all. Faught's

*Do you require or request blood-pressure readings?...
If no:
Do you consider it of no practical value in insurance work, even if obtainable?.....
Do you consider it of value, but unobtainable, or an impractical requirement?.....
If yes:
In all cases?.... Or only over.....years of age?.....
Only over $....application? Only in special cases?....
Is a question as to blood-pressure incorporated in your examination blank?.....
Do you believe blood-pressure readings enable us to exclude certain cases in which other signs often associated with hypertension might not be present or might be overlooked—*i.e.*: trace of albumin, casts, thickened arteries, retinal changes, accentuated second sound, cardiac hypertrophy?.....
Do you believe a risk under sixty years of age is doubtful when the blood-pressure is over 140 mm. Hg, wide cuff?.....
If not, how many mm. Hg would render case doubtful?.....
Do you believe a risk under sixty impaired when blood pressure is over 150 mm. Hg?.....
If not, how many mm. Hg would render case impaired?.....
Have you had cases with sufficiently increased blood-pressure to render case impaired without other evident signs?.....
Do you believe an abnormally *low* blood-pressure has any practical significance in life insurance?
Would an abnormally low blood-pressure, say under 105 mm. Hg. render a case doubtful?.....
Would underweight, or one or more cases of tuberculosis in family, or history of exposure to tuberculosis, have any more unfavorable aspect when associated with a low blood-pressure?.....
Do you ever use or request diastolic pressure or pulse pressure?.....
REMARKS: (Particularly requested and appreciated).

figures were obtained from the larger companies. When I subdivide our replies into those above and below ten million insurance in force, we find that 88 per cent. of the companies having above ten million insurance in force are now using blood-pressure. This comparison and the fact that seven years ago no company requested blood pressure show a rapid increase.

The individual usage of some of the larger and more representative companies, as well as the individual expression of opinion from their medical departments, is of interest. The maximum blood-pressure which could be considered normal varies in the usage of the different companies from 145 mm. to 180 mm. It is worthy of comment that the company which has had the largest experience has the lowest maximum normal blood-pressure. Although there is a hesitancy to express an opinion in regard to the lower limits of normal blood-pressure, the majority are of the opinion that a blood-pressure below 105 mm. should receive investigation. With the warning expressed above against general inferences from individual experiences, I might add several that might seem noteworthy. One medical director writes that he declined a man last fall though everything was favorable but increased blood-pressure. He adds that the man died in March of this year. Another writes of a recent experience, six months ago, where a man thirty-two years of age was rejected solely on account of high blood-pressure. His urine was normal in every respect. The man claimed to be in perfect health. The latest news from this applicant is that he has had two cerebral hemorrhages and is confined to bed. Immediately after the rejection, this man received $10,000 insurance from another company. Another writes that he examined and declined a man sixty-two years of age who had just received a policy from another company. His declination was based on a blood-pressure of 160 m.m. On every other point the risk appeared first-class. Seven weeks later the man dropped dead at his place of business.

In conclusion, I would merely reiterate the position taken in the premises: that instrumental estimation of blood-pressure has become an established clinical sign, and that its usage in life insurance examinations is trending toward a more general acceptance. Coincident with the broadening experience in the use of this method, there is a distinct tendency toward restricting the limits of normal variation.

TRACHOMA.

By M. VICTOR SAFFORD, M.D.,

BOSTON, MASS.

U. S. PUBLIC HEALTH AND MARINE HOSPITAL SERVICE.

It may be noted that over twenty-five different kinds of bacteria have been identified as responsible for the production of inflammatory conditions of the conjunctiva or cornea. This list includes some like the Klebs-Loeffler, leprosy, tuberculosis and colon bacilli, gonococcus, pneumococcus, and others more usually identified with disease processes elsewhere in the body; also staphylococci, streptococci, the Penecillium glaucum, various aspergilli and saccharomycetes. In addition there are others like the Koch-Weeks, Morax-Axenfeld, Petit's, Nedden's bacilli, etc., which appear to be associated with diseases of the eye alone. The resistance of the eye to the various known possible agents of infection varies greatly. Some, as for instance the colon bacillus, seem to require that the natural resistance of the conjunctiva be reduced by trauma or otherwise before infection can occur, while others like the Koch-Weeks appear to be able to attach a perfectly healthy conjunctiva. There is no reason to believe that all bacteria capable of producing conjunctivitis or other inflammatory affections of the eye have been discovered and it is also well known that conjunctival congestion at least may be kept up by many causes other than bacterial infection.

Of the various forms of bacteria which are known to be capable of producing inflammation of the conjunctiva or cornea, some may at times produce a distinctive clinical appearance which suggests at once the cause of the trouble, but this is not always true. The same bacteria do not always produce the same clinical picture and very different bacteria may give rise to similar symptoms. Mixed infections are undoubtedly common and practically identification of the cause of an inflammatory condition of the eye is often complicated by the presence in the secretions of the eye of all sorts of aerobic bacteria and the difficulty of distinguishing the actual cause of the trouble from its accidental companions.

In considering the symptoms to which an inflammation of the conjunctiva may give rise it is necessary to take into account the anatomy of the eyelid. It will be recalled that the surface of the conjunctiva itself although apparently smooth is really traversed by minute ridges and grooves. This condition is capable of becoming greatly accentuated when the conjunctiva is congested and swollen, even causing here and there an appearance which may suggest a beginning granulation process. Scattered through the conjunctiva are also mucous follicles which too are capable of becoming swollen and simulating granulations.

Lying beneath the conjunctiva, interspersed through the connective tisseu of both lids are numerous lymphoid cells, in the upper lid most abundant in the looser tissue back in the retrotarsal fold and the least so where the conjunctiva lies over the tarsal cartilage. The amount of such lymphoid tissue varies normally in different individuals. It is not present in early life and is said to appear at about three years of age. These lymphoid cells exhibit a ready tendency under various conditions to increase greatly in numbers, group together in masses and if the eyelid generally be not at the same time infiltrated and swollen these masses or follicles will push up and show through the conjunctiva, giving what is often referred to as a frog-spawn appearance. Any sort of a persistent irritation of the eye is likely to start this process. The presence of a small foreign body on the conjunctiva for a day or two may prove sufficient. In the upper lid it probably will be noticed first in the looser tissue toward the corners of the eye and back in the retrotarsal fold because here the lymphoid cells are normally more abundant. When this condition becomes extensive and conspicuous it is likely to get called follicular conjunctivitis, even when it occurs in children as a concomitant of adenoids.

In this simple proliferation of the subconjunctival lymph cells the resulting follicles or frog spawn will be found on close examination to be soft and compressible, there will be no indication of structural damage to the overlying conjunctiva, and no matter how long the condition may exist when it finally disappears the conjunctiva will be restored to its normal appearance. Subconjunctival lymphoid proliferation is not a disease but a symptom, and a symptom and accompaniment of so many pathological conditions of the eye as to be practically without diagnostic value whatever.

Increase in the subconjunctival lymphoid tissue may be accompanied by hyperplasia of the subconjunctival connective tissue as well. This may occur of course in connection with ulceration from traumatism or from destructive inflammatory changes of any sort. In three instances, however, all from causes as yet unknown, a lymph cell proliferation and connective tissue hyperplasia are associated with histological changes in the eyelid and clinical manifestations so distinctive in character as to have lead to the differentiation of these three processes into three separate diseases. In one instance, so-called vernal conjunctivitis, *frühjahr catarrh,* or more appropriately, periodic hyperplastic conjunctivitis, there is a great general increase of the subconjunctival connective tissue, both elastic and fibrous. The effect of this connective tissue hyperplasia with its accompanying lymph cell infiltration of the lid and epithelial

changes is both to hump up and fissure the palpebral conjunctiva, giving it a tessellated appearance comparable to an old street paved with Belgian blocks in bad repair. Clinically this affection is also distinguished by its periodicity and by the fact that it shows no tendency to destroy the conjunctiva, leaving it after periodic attacks covering seven or eight years practically undamaged.

In another instance, Parinaud's conjunctivitis, there is a diffuse formation of new tissue greatly infiltrated with loose lymph cells and tending to the production of polypoid vegetations of the eyelid. When fully formed the clinical appearance as well as the microscopical structure of these vegetations is absolutely distinctive. The onset of this disease is characterized by general constitutional disturbance and by swelling or even suppuration of the preauricular glands and possibly other glands in the vicinity. There may be some localized ulceration of the conjunctiva as an accidental consequence of the symptoms of the disease, but the disease usually disappears without causing permanent changes in the eyelid from destruction of the conjunctiva or otherwise.

In the third instance in which a characteristic connective tissue hyperplasia occurs in the eyelid, as the lymphoid cells proliferate the follicles tend to degenerate and to become encapsulated by the newly formed connective tissue. In connection with this process new blood vessels are also formed which permeate to some extent the interior of the follicle. As the inflammatory process continues these little round, firm capsules are pushed up into the conjunctiva. Their contents break down. The overlying conjunctiva becomes involved in the same degeneration and gives way. The contents of the capsule are discharged and the little spot of destroyed conjunctiva is replaced by scar tissue. In this way the disease tends to destroy bit by bit the entire conjunctiva. As a result also of the changes which take place beneath the surface there is a permanent obliteration of the normal blood vessels and a general atrophy of the lid.

This is the disease which the United States Government recognizes as trachoma. The pathological changes as shown by the microscope in a section of a trachomatous eyelid are absolutely characteristic, but such procedure is of course not practicable for diagnostic purposes. What, therefore, has been taken as the essential diagnostic feature of the affection is the formation of firm organized follicles which coalesce with the conjunctiva, break down and cause its progressive destruction. It is on the demonstration of this process that officers of the Public Health and Marine Hospital Service are instructed by their regulations to rely as furnishing the conclusive evidence requisite for the issuance of a medical certificate that any immigrant is afflicted with the disease.

In considering other and incidental clinical manifestations of trachoma, especially in the light of the experience which has been gained by medical officers of the Public Health and Marine Hospital Service in their examination of the eyes of 14,000,000 people of all nationalities and their practice of holding abnormal conditions of the conjunctiva under observation *ad libitum*, the following mentioned general conclusions seem justifiable. In its onset trachoma is clinically indistinguishable from a conjunctivitis from any other cause. It may come on as a violent inflammatory affair. The original infection, alone or mixed, may produce an ophthalmia which may quickly destroy vision. The type of the disease with a more or less violent onset appears to be emphasized in the literature regarding the affection, probably because these are the cases usually recognized early. The experience gained in the examination of immigrants at both ports of departure and arrival certainly warrant the belief that the initial conjunctivitis is ordinarily a comparatively mild affair. The disease often seems to come on insidiously without sufficient inflammatory reaction to cause an individual to give up work or seek medical treatment. A pronounced inflammation of the palpebral conjunctiva without corresponding involvement of the ocular conjunctiva and a secretion rather watery than purulent are suspicious signs. A mild conjunctivitis from unaccountable cause persisting in spite of intelligent treatment is still more suspicious. But the writer knows as yet of no trustworthy indications of a trachomatous process until the appearance of the firm hyperplastic granules, which not only push up but also involve the overlying spot of conjunctiva. Even when the disease has actually reached this stage the granules may be so masked by the general swelling of the lid as not to be demonstrable until the acuter inflammatory symptoms have subsided. The writer is inclined to believe that trachoma ordinarily begins with an infection of the lower lid and that it is there that the first signs of granulation will appear. The disease process in the lower lid however does not take place under the same mechanical pressure as in the upper lid, and for this reason probably its manifestation in the former are less pronounced and more likely to be overlooked. The writer also believes that the trachomatous process leaves there a scarring which would always be characteristic if not obscured by the changes so likely to be produced in the lower conjunctiva from various irritative causes by the time adult life is reached. The time which may elapse from the onset of the disease until distinctive granules become visible in the conjunctiva varies considerably. In a case which recently came under the writer's observation seven weeks elapsed from the time troublesome subjective symptoms became manifest until even suggestive indications of a trachomatous process appeared. Until then the disease presented itself as a mild but more or less annoying conjunctivitis of an indefinite character. This case it might also be noted received medical treatment in hospital from within three weeks after the subjective symptoms were stated to have appeared, and in an effort to account for the resistance to treatment an exhaustive bacteriological study was made of the eyes and the patient even subjected to a tuberculin test, all with negative results. Ordinarily, however, in the writer's opinion, some fairly definite indications of a trachomatous process may be expected to become visible within two or three weeks from the onset of inflammatory symptoms.

The chances for error of diagnosis which may exist in connection with the recognition of the earlier stages of trachoma cannot be too strongly emphasized. Under the practical conditions often presented, swollen conjunctival corrugations, swollen mucoid follicles, or simple lymphoid follicles may be mistaken for a beginning trachomatous process. It may be stated without qualification that the cases of supposed active trachoma which yield readily to treatment actually belong

in this category. What is still worse the recognition of the true character of the three conditions just mentioned is very likely to lead experienced oculists to overlook a true coexisting trachomatous process, even after some localized destruction of the conjunctiva has actually begun. The fact to be emphasized is that all these conditions may proceed or accompany a trachomatous process. Trachoma and a typical follicular conjunctivitis may coexist on the same lid, perhaps owing to some causal relationship or perhaps purely as the result of superadded infection. In connection with the avoidance of diagnostic errors in abnormal conditions of the eyelids three or more or less neglected factors might be mentioned which are equally as important as a recital of pathological differences. They are: A familiarity with the appearance of an ordinary, substantially normal conjunctiva, including both the inferior and superior culs-de-sac. A practice, when examining an eyelid, of invariably pressing down and exposing to view the retrotarsal fold of both eyes. A beginning trachomatous process is always seen most distinctly in the retrotarsal fold. Third: Sufficient dexterity to be able to evert an eyelid and thoroughly expose this fold to view in the case of an ordinarily sensitive inflamed eye without causing such a spasm of the ocular muscles as to produce an engorgement of the tissues and thus make a satisfactory examination impossible.

The trachomatous process may involve the ocular conjunctiva, but the disastrous effects on vision commonly associated with trachoma are rather in the nature of accidental consequences of the process which takes place in the eyelids. The attrition of the roughened trachomatous tarsal conjunctiva tends steadily to impair the transparency of the cornea. It may be that in this way a true trachomatous process is maintained on the eyeball itself. Pannus has usually been regarded as an indication of such a result and to be a certain diagnostic sign of trachoma. As the disease becomes more advanced and the inner surface of the eyelid becomes scarred and contracted the resulting entropion may bring the rough margin of the lid or the eyelashes themselves against the cornea, subjecting it to still greater irritation. The constant irritation of the eyeball from these sources with its maceration in abnormal secretions tends not only to impair vision itself, but to render the eye susceptible to superadded accidental infections of all sorts. It is to these intercurrent infections, or in other words to mixed infections that, the writer believes, the acute exacerbations seen in the course of the disease, the destructive corneal ulcerations and blindness is ordinarily due.

The writer has seen too much of the horrible results of trachoma not only among foreigners, but among the unfortunate inmates of orphan asylums in this country, to wish to underrate the dangerousness of the affection, but the work of the medical officers of the Public Health and Marine Hospital Service during the last fourteen years seems to justify the conclusion that in localities where the disease is prevalent trachomatous infection is much more common and less uniformly disastrous in its results than is often supposed. The acquaintance of the medical profession generally with trachoma is apt to be limited to the type and stage of the disease which is calculated to lead even the most stupid and ignorant to seek medical relief. But in our wholesale examination of the eyes of immigrants from regions where trachoma is notoriously prevalent, cases are continually being met in which the trachomatous process is proceeding steadily with the destruction of the conjunctiva without causing marked inflammatory reaction or even serious discomfort. Often cases are seen in which in one eye or both the disease has become spontaneously arrested before the destruction of the conjunctiva has become complete. It is reasonable to suppose that the seriousness of the manifestation of trachoma may vary with the virulence of an original or intercurrent infection, but the writer believes that there is a large mechanical factor in this matter as well, depending on the natural looseness or tightness of the individual's eyelid. Given an eyelid which fits tightly over the eye there is going to be serious trouble from the start, while in persons with naturally loose, flabby eyelids the conjunctiva may be found to have been entirely destroyed without producing noteworthy damage to the cornea or sufficient entropion to give rise to trichiasis.

The cause of trachoma is unknown. Mechanical irritation or inflammation from any known causative agents, no matter how long-continued or how virulent, fail to start up the trachomatous process. The healed ravages of a gonorrheal infection or the final result of gross ulceration from trauma or other cause produce in an eyelid changes which are usually easily distinguishable from a cicatrized trachomatous process. The minute pathology of this process points to some infective agent. The trachomatous process from its beginning suggests a clumsy effort of nature to bring about the extrusion of irritative material which has found its way down into the subconjunctival tissue. It is of course conceivable that this process might be set going as an accidental consequence, as it were, of various kinds of infective bacteria finding their way down into the subconjunctival tissue. Such a supposition would seem to fit very well with the variations seen in the severity of symptoms, and the apparent difference in the degree of contagiousness of the affection. The writer has been inclined to this view, but in the face of a steady accumulation of circumstantial evidence to the contrary feels forced to conclude that such a theory is untenable. The more that one goes into this matter the stronger the evidence appears to be that hyperplastic granular destruction of the conjunctiva, no matter how limited in extent or mild in its symptom, is due invariably to a single infective causative agent.

As to the contagiousness of trachoma. There are many honest, well-meaning individuals who maintain that smallpox is not contagious, and support their contention by more or less plausible arguments. Arguments that trachoma, as described in the foregoing, is not a distinct disease spread by affected individuals, belong in the same category. We find no difference of opinion as to the contagiousness of trachoma among those who have achieved any success in actual efforts to check the spread of the disease. For a hundred years its contagiousness has been recognized in continental Europe as the cause of one of the most troublesome problems of military hygiene. On the long voyages from Italy to South America on emigrant ships the Italian Government has found it necessary to segregate in a special part of the ship those passengers who are found after a specially prescribed medical examination by governmental offi-

cers to be afflicted with trachoma even though the countries to which they are going do not as yet exclude trachomatous immigrants.

In the present state of knowledge as to the etiology of trachoma, deductions as to its contagiousness must of course rest on the same sort of evidence as that on which conclusions usually must be based in human affairs. Four children carefully guarded in a luxurious home suddenly develop trachoma and in spite of skilled treatment one of them becomes totally blind. On investigation a recently arrived immigrant girl employed in the family is found to have an unsuspected case of trachoma so far advanced in the cicatrical stage as to be commonly regarded as innocuous to others. Two members of a similar household develop serious cases of trachoma. A servant who has been employed in the family goes on a visit to Europe. On her return her employer finds that she has been stopped at Ellis Island on account of an old long-standing case of trachoma of a benign type. It takes something more than mere theorizing to satisfy one who has seen trachoma spread through an orphan asylum, and has from time to time seen doctors and nurses being treated for the disease after association with trachomatous patients, that the natural conclusion in the above-mentioned instances is not correct.

As to the matter of immunity to infection. On the S.S. *Oldenburg*, arriving at Baltimore in February, 1907, sixty-seven persons from the same compartment were found to be suffering from an inflammatory affection of the eye of the same general type, the origin of which was apparently due to the presence in their midst of four cases of trachoma in a state of acute exacerbation. Of these sixty-seven affected passengers forty-eight subsequently developed trachoma, while the remainder promptly recovered under simple remedial measures.* In the writer's fifteen years' experience in the medical examination of immigrants he has never yet found a well-established active case of trachoma in an immigrant family which has been living together in the same house without discovering other members of the family also affected. When he has thought he has found such an instance investigation has always brought out the fact that the diseased individual has not been living at home. On the other hand, he can recall instances of families of as many as twelve members all so diseased, the parents practically blind and the children presenting successive gradations toward the same stage. The impression that one member of a family may have trachoma and others escape is probably due to the fact that the others may have a type of the disease which does not give rise to conspicuous symptoms and consequently passes unrecognized. So also in those instances in which trachoma appears to be confined to one eye a more careful examination will usually reveal a milder or arrested case of the disease in the other. The writer has, however, seen cases in which there were no discoverable signs of disease except in one eye but similar instances have been reported even in the case of a demonstrated gonorrheal infection.

In contagious inflammatory eye affections it seems safe to assume that the danger of contagion is directly proportional to the amount of secretion. This probably holds good for trachoma. But it begins to seem that in affections of this general character danger of contagion is not entirely obviated by the adoptions of means to prevent the direct conveyance of infective material to the eyes of a second person as by the medium of a towel or soiled fingers. Military surgeons in Europe have long persistently declared that trachoma has continued to spread among troops after the possibility of such means of contagion has been positively eliminated. In connection with the study of the spread of other forms of conjunctivitis whose bacterial cause is known, recent observers seem inclined to emphasize the danger of the spread of such affections in two other ways, directly by sneezing or coughing and through the medium of dust. In this connection they point out that the secretions of the eye naturally drain down into the nose and throat and when the infective bacteria are sneezed or coughed out they are enveloped in a watery pellicle which serves to prolong the vitality of those which are susceptible to drying. Attention has also been called to the fact that when introduced in the eye in connection with dust they are accompanied by a mechanical irritant which may facilitate infection.

The matter of the contagiousness of trachoma possesses much more than academic interest. The United States Government regards trachoma, except in a healed cicricial stage, as a dangerous contagious disease, and denies admission to the country to all foreigners so afflicted. This action taken by the Government in 1897 because of evidence that the newly developed immigration from southern and eastern Europe was spreading trachoma in this country to an alarming extent. The policy of excluding trachomatous immigrants appears to have had the desired effect. In some of our cities eye clinics then occupied almost entirely with the treatment of trachoma, have been closed from lack of material, and in many localities an acute case of trachoma has come to be looked on as a curiosity. As the policy of the Government has tended to accomplish its purpose the old conditions which led to the adoption of that policy have been gradually forgotten. In the meantime immigration from eastern Europe and Asia has been constantly increasing. In the last ten years also immigrants denied admission at our ports of arrival because of trachoma have increased from one in eighteen hundred to one in four hundred, and this too in spite of the refusal of the transportation companies to accept trachomatous individuals for passage, and the adoption of more and more rigorous measures to prevent them from getting aboard ship at foreign ports of embarkation. The number of people thus held back from attempting to come to this country has been augmented each year. Today the policy of our Government in regard to trachoma is the sole obstacle in the way of the migration to this country of hundreds of thousands of trachomatous inhabitants of Europe and Asia who are bound by racial and family ties to people that have already come here and now form an integral part of our population.

The Relation of Trachoma to the Administration of the United States Immigration Laws.— The uphill struggle in which this country has been engaged for over seventy years to devise effective means for the control of the conduct of the immigrant traffic has always had three distinct purposes

*"Trachoma. Its Character and Effects," Passed Assistant Surgeons T. Clark and J. W. Schereschewsky, U. S. Public Health and Marine Hospital Service: Government Printing Office, 1907.

in view. They have been to prevent the bringing into this country of certain obviously and seriously objectionable classes of individuals, to protect the country against the accidental importation of exotic epidemic diseases, and to safeguard the personal welfare, physical and economic, of the immigrants themselves. The means by which it has been sought to attain these ends have proved to a great extent ineffectual. The earlier measures devised under State authority have been largely superseded by Federal legislation, the execution of which has fallen from time to time to different branches of the Federal Government. That portion of existing Federal laws relating to the exclusion of foreigners from the country and providing for the protection of immigrants against "fraud and loss" has been placed in the hands of a branch of the Federal Government especially created for the purpose, the Immigration Service. These laws require that the right of every foreigner to enter the country shall be passed upon by officers of this Service who, after a prescribed method of examination, shall decide whether or not any individual may belong to any of twenty specifically defined classes which the law says are inadmissible. Twelve of the classes so enumerated, among which are "insane persons," "persons likely to become a public charge," under certain conditions persons having a defect "affecting ability to earn a living," "persons afflicted with a loathsome or dangerous contagious disease," etc., call for the possession on the part of the immigration officials of authoritative information regarding the physical and mental condition of every alien applying for admission. Since 1891 the task of supplying such information to the immigration officials has been a part of the work of the U. S. Public Health and Marine Hospital Service. Medical Officers of this Service are required by law to certify for the information of the appropriate immigration officials any and all physical or mental defects or diseases which arriving aliens may have. Medical certificates or statements submitted by duly authorized medical officers of the Public Health and Marine Hospital Service, after compliance with the regulations of their own Service applicable in the premises, are made by law final and conclusive in the matters to which they relate.

Since 1891 nearly 14,000,000 alien arrivals of every race and nationality have come before these medical officers for physical and mental examination at the ports of entry of the United States and its possessions, and of Canada. In addition officers stationed at Asiatic and to some extent at European and tropical American ports have been called upon to examine prospective passengers with reference to the requirements of our immigration laws, as well as to secure enforcement of our quarantine laws and regulations. During these twenty years the Public Health and Marine Hospital Service has been steadily utilizing the experience thus gained by its own officers, together with the benefits of general progress in medical knowledge and special help from various sources in a systematic effort to put this branch of its work on a plane of efficiency and uniformity that will enable it to fulfill the purpose contemplated in the immigration laws.

The detection of diseases and defects among arriving passengers still depends largely, but by no means entirely, on such a "primary medical inspection" as forms a conspicuous feature of the work of the medical officers at Ellis Island. To the casual visitor this process may seem hasty and superificial, but the wide range of diseases and defects comprised in the list of "cases certified" in the course of a year shows better the extent to which the possibilities of such a systematic scrutiny of arriving passengers has been developed. The cumulative experience and study of the past has led to the adoption of certain definite rules for the conduct of this process and newer men are trained at once in their application. But official regulation of the conduct of the medical examination goes still further. This "primary medical inspection" aims solely at the segregation of the obviously defective and suspects of any sort. It is not concerned with the matter of diagnosis. To insure uniformity, guard against diagnostic or clerical errors, and to preserve compliance with court decisions and authoritative legal opinions of the executive departments of the Government with reference to the meaning of medical terms used in the law, the subsequent conduct of the medical examination work is also largely prescribed in detail by official regulations. Neither law, regulations, nor custom places any limit on the time which medical officers may take to insure an accurate diagnosis in any case. Three or four weeks is not an unusual period of detention for this purpose. By existing regulations medical officers are instructed "not to render a certificate setting forth the person concerned to be the subject of any physical or mental defect or disease unless the existence of such defect or disease rests upon conclusive evidence." In many instances, also, the regulations state specifically what evidence is to be regarded as conclusive. The acts of an individual officer are furthermore subject to a system of checks and reviews which operates to put the conduct of the whole medical work at the larger ports of entry on a basis comparable to a modern business management, and to so safeguard the interests of an immigrant as to make his deportation to-day by reason of an unjustifiable medical certificate a practical impossibility.

The scrutiny of the eyes of arriving immigrants is naturally a conspicuous feature of the "primary medical inspection." It is necessary to be on the watch to follow up the hint which may be furnished by a puckered face, a corneal opacity, a drooping lid, nystagmus, strabismus, any evidence of inflammation, or any other abnormal sign not only as regards the possibility of indicating some local affection, but any constitutional disease as well. Unequal pupils, for instance, may arise from various causes, and may have slight practical importance, but they have repeatedly led to the detection of cases of beginning paresis.

In 1897 this matter of the disposition of inflammatory eye affections began to assume a new importance. Among the classes of aliens expressly declared by the immigration laws to be inadmissible to the country are "persons afflicted with a dangerous contagious disease." In that year, as the result of persistent representations from oculists and municipal authorities in various localities to the effect that trachoma was rapidly spreading in this country as the result of its prevalence among immigrants and constituted a serious public menace, the Secretary of the Treasury invoked the authority which was then vested in him by law to declare trachoma to be a dangerous contagious disease, and to instruct immigration officials to exclude from admission to the country all aliens so afflicted. Prior to this time it had been customary for the

medical officers engaged in the medical examination of arriving immigrants to certify marked cases of trachoma for the information of the immigration officers, pointing out the danger to eyesight, the probability of recurrent attacks of acute inflammation calling for treatment, and the possible contagiousness of the affection. As a result, some of the severer cases were excluded as "likely to become a public charge," but little or no attention was paid to the milder types of the disease even if detected. Cases of acute eye inflammations, whether due to trachoma or not, calling for immediate treatment, were then, as now, placed in hospital and action deferred until sufficiently improved to be able to travel.

This order added nothing to the already existing duty imposed on the medical officers by law of detecting and certifying "any and all physical and mental defects or diseases." The Service to which these officers belong was thereby placed under no greater obligation to devise methods for the detection of trachoma and to formulate regulations that would safeguard against errors of diagnosis than in other instances in which an alien's admissibility might hinge on the results of the medical examination. But as the result of this order a situation rapidly developed which has stimulated the Public Health and Marine Hospital Service to direct special attention to the matter of the etiology and diagnosis of trachoma, and has led to the adoption of special precautions to prevent the issuance of medical certificates for trachoma except on conclusive evidence of the existence of the disease.

When this order went into effect it was nothing unusual to find at New York among the passengers on a single ship sixty or seventy typical textbook cases of trachoma, with eyesight in various stages of impairment. The detection and diagnosis of such cases presented no difficulty. In addition, hospital accommodations were swamped with cases of apparently acute conjunctival inflammations. These it had usually been the practice to discharge when acute symptoms were relieved in order to make room for new arrivals. As closer attention began to be directed to the diagnosis of trachoma it soon became apparent to both the medical officers and the local oculists, whom it was customary to call on for assistance at that time, that many of these presumably transitory cases of "catarrhal" conjunctivitis were in reality cases of beginning trachoma due to recent infection. Complaints were made by municipal authorities as late as 1903 that the medical examination to which immigrants were being subjected at the chief ports of entry was failing to keep cases of trachoma out of the country as intended by the order of 1897. Even to-day officers conducting this examination are confronted from time to time by an aggravated case of trachoma in an alien resident of this country who had been noted at the medical examination on his arrival some months previously as having what was regarded as an inconsequential ocular irritation.

It is to be observed that in 1897, when complaints in regard to the spread of trachoma reached their climax, the newer type of immigration to this country was coming into prominence. With the development of the immigrant traffic in Southern and Eastern Europe, and the lessening attractions of this country to people of Northern and Western Europe, we were coming to draw our immigration more and more from countries where trachoma is extremely prevalent, affecting in some localities nearly the whole population, instead of, as formerly, from that part of Europe where the affection is relatively uncommon. We are now not only drawing immigration from Eastern Europe but from as far into Asia as Persia. In the exploitation of emigration from this whole region of Southern and Eastern Europe and Western Asia a constant obstacle has been encountered in the policy of this Government with reference to the exclusion of aliens afflicted with trachoma. At a conference at which the writer was present, four years ago, it was stated by a representative of the transportation interests that the steamship companies were then rejecting in Europe on account of trachoma over 100,000 actual applicants for passage a year. At prevailing rates for passage these actual rejections alone would represent a loss to the transportation and allied interests in gross income of not far from $4,000,000 annually.

As time has gone on there has been a constant accumulation of people in Europe and Asia whose emigration to this country has been checked by reason of the fact that they are afflicted with trachoma. Their relatives and compatriots who have come to this country have likewise been increasing not only in numbers, but in wealth and political power. These latter are naturally interested in securing the admission of those who are now prevented from joining them here, and this interest is developing into a powerful organized movement to bring about a modification of the present policy of this Government in regard to the disease. Indications of the progress of this movement are constantly apparent. Out of 24,270 aliens refused admission at our ports last year only 2618 were excluded by reason of trachoma and a considerable proportion of these undoubtedly contracted the disease from fellow passengers en route, yet how often is mention made in the newspapers of an immigrant being deported for anything else? The hardships of deportation in such instances are minutely dwelt on. Trachoma is pictured as a sort of bugaboo of the "immigration doctors," and allegations that it is not contagious at all are given the widest publicity. Criticism of the medical officers is nothing new. They have always been charged from various sources as being "inexperienced," "overzealous," and "incompetent." When after the observance of all precautions against error, a certificate of trachoma, or, for that matter, some other disease, has been issued, and the exclusion of an immigrant has resulted, it has been a common occurrence to have to defend the certificate against medical testimony produced by the immigrant's attorney to the effect that the disease stated in the certificate does not exist.

Under stimulation of the character above referred to and with the possibility of trachoma ever present in mind, these Government medical officers during the last fourteen years have examined the eyes of nearly 10,000,000 Europeans, Asiatics, and Africans. In probably 7,000,000 instances this examination has at least included an eversion of the upper lids and the pressing down and exposure to view of the superior retrotarsal fold of conjunctiva. In an unknown number of instances, but probably reaching into the hundreds of thousands, persons showing indefinite inflammatory conditions of the conjunctiva have been held under observation and studied for periods varying from a few days to several weeks until the conjunctiva has regained a practically normal appearance or until conclusive evidence of some definite disease has developed. Noteworthy research work in tra-

choma being done anywhere in the world has been watched for and followed, in many instances personally, by some officer of the service who happened to be near. Officers who have had opportunity to study trachoma while stationed in Europe or Asia, or among the natives of Alaska, have added their experience to that gained at our own ports of entry. But while in this way a vast amount of clinical knowledge of inflammatory conjunctival conditions has been accumulated and applied to the conduct of the medical examination of immigrants it has failed thus far to supply any quick and easy method for the recognition of incipient or atypical cases of trachoma. The Government still rests the diagnosis of trachoma on clinical evidence. As practically from the beginning the instructions to medical officers contained in official regulations still regard the essential clinical feature of trachoma to be a hyperplastic granular destruction of the palpebral conjunctiva. The demonstration of this destructive process is regarded to be the conclusive evidence requisite to the issuance of a certificate that any immigrant is so afflicted. By these instructions it is furthermore required that all arriving cases of inflammatory conjunctival affections shall be held under observation to see if such evidence of trachoma may appear, or until the inflammation disappears or is otherwise satisfactorily accounted for.

MANIC DEPRESSIVE INSANITY, THEN SYPHILIS, LATER GENERAL PARALYSIS.

By W. F. LORENZ, M.D.,

MENDOTA, WIS.

The sequence of events, as illustrated in this case, is extremely rare and the relationship of syphilis to general paralysis is further emphasized.

C. M. was admitted to the Wisconsin State Hospital April 5, 1911. Male. Age 41. Single. Salesman. Family history is practically negative. The paternal grandmother died of a "stroke" at the age of 64. Reliable and detailed information as to the various members of the family was obtained and was of no significance. Personal History: During infancy nothing of note occurred, and as a boy patient was considered a bright and active youth. He made good progress at school, was socially inclined, enjoyed sports, and was generally active and progressive. After leaving school he was employed in the office at Racine College.

First Psychosis: At the age of 21, the patient developed his first depression and it was described by the relatives as a "melancholia." This was of short duration, and he made a complete recovery, returning to his work until the following year, when a similar depression occurred. This was again followed by recovery. In the spring of the year following, or at the age of 23, a third attack occurred, and the informant emphasized the fact that this attack was different from the two former. They describe him as having been "extremely unbalanced" and more especially that his mood was elevated and he was generally overactive. It became necessary to send him to a hospital, and he was admitted to a private institution at Wauwatosa in April, 1893, where he remained four weeks. He was then transferred to the Northern Hospital. Unfortunately, the records are rather meager, although the dates of admission and discharge are unquestionable. He was admitted to the Northern Hospital May 1, 1893, and the notes made at that time describe him as being "profoundly melancholic." Subsequently in the history statements are made which would indicate that the patient's mood altered to one of elevation with overactivity, since he was described as having become "deranged on subject of finances and constantly writing checks, etc." Finally he was described as becoming well-behaved, quiet, and was discharged as recovered October 20, 1893. Following his discharge from the hospital, the patient secured employment as a canvasser for baking powder and was successful. Nothing abnormal was noticed in his behavior and he was considered mentally sound and capable. In 1903 he contracted syphilis and had well-marked secondary manifestations. A rigid mercurial treatment was given for eighteen months and nothing of consequence occurred until the onset of his present trouble.

Second Psychosis: For several years previous to his present admission it was noticed that the patient's business ability fell off and that he did not display the same interest and vigor that he formerly had, although he continued at his work until the winter of 1910, when he became extremely indolent, remained at home all day, lying on the sofa, and became generally careless and indifferent. About one month previous to his admission he became very restless and began expressing peculiar ideas. Concerning his habits, he was thought to be temperate in his use of intoxicants, but was decidedly immoral in his tendencies.

Mental examination upon admission showed a typical case of general paralysis. The patient was absurdly expansive; owned fabulous sums of money; fraternized with millionaires and financiers; he was extremely euphoric and his memory was very faulty, especially for dates, in giving which he made gross discrepancies. Physical examination likewise gave evidence of a general paralysis. The pupils were unequal and Argyll-Robertson in type, the deep reflexes were exaggerated and the knee-jerks were unequally so; the Romberg symptom was present, as was also a marked tremor of the extended fingers, lips and tongue; the patient had the characteristic speech defect and tremulous and irregular writing; there was a scar on the glans. Lumbar puncture was positive; the fluid showed an average of 73 lymphocytes per c.mm.; a very positive Noguchi butyric-acid test, and a well-marked first and second phase of the Nonne-Apelt test.

The two early depressions, episodal in their nature, with a subsequent attack, probably of the circular variety, would surely warrant the conclusion that the patient had a manic-depressive psychosis. Ten years after his first hospital admission he contracted syphilis and approximately seven or eight years after this infection showed signs of mental failure. It is to be noted that the mental picture at present is the usual expansive form of paresis and the existence of a previous psychosis in no way colored the clinical manifestations of the paresis.

ON THE OCCURRENCE OF SO-CALLED HENOCH'S PURPURA, WITH REPORT OF A CASE.

By JOSEPH LEWI BENDELL, M.D.,

ALBANY, N. Y.

Blood spots or hemorrhagic areas occurring in the skin as an accompaniment of diseased processes were observed and described by physicians of antiquity. It remained for Werlhoff, in 1775, to first differentiate such conditions as definite clinical en-

tities, the term purpura hemorrhagica being designated to describe the conditions. Subdivisions later on included the terms purpura simplex, designating what probably to-day we should consider as a simple purpura, and purpura urticans, in which marked itching of the skin was a feature of the disease. Finally Schönlein grouped together certain ill-defined rheumatoid manifestations in conjunction with purpuric spots and coined the term peliosis rheumatica. To-day, in honor of its originator, we use the term Schönlein's disease, thereby designating groups of arthritic disorders associated with hemorrhagic infiltrations into the skin.

All of the above classifications depend more upon symptomatic pictures than upon any definite pathological basis. Hence the distinctions were more artificial than real. In order to gain a better understanding of the disease, Osler has divided the purpuras into two groups, the one symptomatic, the other arthritic. He considers the symptomatic purpuras those in which purpuric lesions exist simply as a part of the diseased process, recognizing at the same time a definite etiological factor. Under this heading are included infectious diseases, such as smallpox, measles, scarlet fever, typhus, and ulcerative endocarditis.

The second subdivision of the above group we may term the toxic purpuras or those dependent upon certain drugs, such as quinine and the iodides; or again icteric purpura, and lastly ecchymoses, dependent upon the bites of venomous snakes. Third, cachetic conditions, viz., carcinoma, tuberculosis, and nephritis, diseases which, if protracted, not infrequently produce the lesion in question. Fourth, certain nervous states among which may be mentioned tabes, where occasionally the stabbing pain in the extremities is accompanied by purpuric disorders, and infrequently the intense forms of hysteria. Fifth, mechanical causes, slight bruises and straining efforts during whooping cough. Litten reports a case in this group following the administration of an anesthetic that was poorly taken.

The second great group, the arthritic purpuras, may be divided into purpura simplex, purpura rheumatica, and purpura hemorrhagica. No hard and fast rule obtains in the above classification. Thus in purpura simplex joint symptoms are entirely absent, a slight series of ecchymotic spots being the principal lesion. In purpura hemorrhagica bleeding from mucous membranes dominates the picture, whereas in purpura rheumatica the joint symptoms predominate.

The type of disease with which we are chiefly concerned in this paper, differing as it does from the other forms hitherto mentioned, was first described by Henoch, the so-called Henoch's purpura. Henoch was the first to definitely study and classify a group of purpuras that in addition to the purpuric eruption and arthritic manifestations presented abdominal symptoms. Willan, several years prior to Henoch, published the report of a single case of what we now classify as Henoch's purpura, but the latter was the first to describe as a clinical entity the disease now by common consent bearing his name. This particular type of purpura is at the present time, in no wise regarded as having a different pathogenesis from the other forms. It is considered merely as representing a severe blood dyscrasia plus marked gastrointestinal symptoms. The disease occurs principally in the early years of life. The maximum number of cases are encountered between the ninth and twelfth years. Beyond the fourteenth year it is rarely found, although the age in our own case was fifty-three. Males are more prone to the disease than females; of a series of forty cases, thirty-three were males and seven females. Poor hygienic surroundings, lack of proper nourishment, and previous rheumatoid attacks are considered among the etiological factors favoring the occurrence of the disease, although the condition is frequently found among the well-to-do and well nourished. Mention is made of the latter point since formerly much stress was laid upon poor conditions of nourishment, as predisposing toward purpuric states, the later associated in this instance with scurvy.

The disease is commonly ushered in with symptoms of headache, depression, and general malaise. Indefinitely situated rheumatoid pains, lancinating in character, are met with during this early stage and sometimes transitory edematous swelling of the affected regions may be seen. These symptoms are soon followed by swelling of the joints and the usual symptom-complex of acute articular rheumatism. During this stage of the disease isolated purpuric spots may be discovered. The latter are usually light red and small in the beginning, distributed irregularly, singly or in groups, gradually becoming large and tending to become confluent. As the disease progresses, their color changes from a light red to a dark purplish black, going through the various color changes due to transition from one pigment stage to another. The purpuric eruption usually begins on the legs and extends to the genitals and abdomen and sometimes covers practically the entire body. During this stage of the disease we begin to get the usual train of toxemic symptoms such as heightened temperature and pulse rate coupled with depression. The appearance of the gastrointestinal syndrome now follows. Violent colicky abdominal pains set in. The abdomen becomes extremely sensitive, in this particular point the conditions resembling one of general peritonitis because of the pain and rigidity. Nausea and vomiting set in, the vomitus at first consisting of food mixed with bile and later on containing blood. In our own case diarrhea was a persistent symptom. Numerous blood-stained evacuations continued from time to time, no remedy apparently being able to control the condition. In certain atypical forms of the disease in which hemorrhage from mucous membranes is absent large ecchymotic areas appear suddenly and rapidly become confluent so that the entire surfaces of the limbs become brawny and deep purple in color. Because of the rapidity of the process, this type of the disease has been termed "purpura fulminans." But a few cases have been reported, all of these proving rapidly fatal within a few days of the onset, the longest duration of any of them being four days. The autopsy in one of this series showed nothing but evidence of intense anemia, no embolic or thrombotic processes being discovered.

The following case, reported through the courtesy of Dr. Edgar A. Vander Veer, on whose service it occurred, is as follows:—

Mrs. A. B., age 53 years, U. S., married, entered the Albany Hospital complaining of swelling in arms and legs. Family history, negative; mother of five children who were alive and well. For several years menstruation had been irregular and scanty. Has had several previous attacks of arthritis, involving the ankles, shoulders, and wrists, complicated with slight hemorrhages from the

gums. In 1899 first noticed a swelling in both legs and arms associated with reddening of the skin which later on was followed by the appearance of purpuric discolorations in these parts. The patient claims that, although she has long been subject to rheumatic attacks, the swelling of the limbs with the accompanying purpura bore no relation to the attacks of arthritic pain. About two weeks before the patient entered the hospital she noticed a swelling of both arms and legs accompanied by discoloration of the skin in certain areas covering these parts. These symptoms appeared suddenly and have persisted. There is some difficulty in urination, pain occurring just after micturition. She complains of feeling sick and faint after eating but there are no other gastric symptoms. The history is otherwise negative.

The patient is a well-developed but poorly nourished individual. Skin and mucous membranes are somewhat pallid but there is no marked anemia. Temperature 99°, pulse 78, fair quality. Blood-pressure 140 mm. Covering the extensor surfaces of both legs and arms are numerous ecchymotic patches varying in size from a ten-cent piece to large irregularly shaped patches covering an area five or six inches in diameter. Both arms and legs are moderately swollen. The abdomen is somewhat distended and likewise presents purpuric spots resembling those covering the limbs. The abdomen is also somewhat sensitive to pressure and is painful. Physical examination is otherwise negative. The urine contains a faint trace of albumin, a few finely granular casts, and a few leucocytes, slightly acid and sp. gr. 1020; leucocytes, 13,200; erythrocytes, 3,560,000; hemoglobin 80 per cent.

The patient presented no unusual symptoms until the eighth day after entrance, at which time the temperature jumped from 99° to 104°, the pulse mounting from 80 to 116. At this time the patient had a bloody bowel movement and complained of intense colicky abdominal pain with nausea. From this time on the patient's condition grew steadily worse. The temperature remained for the most part in the neighborhood of 102°, the pulse oscillating between 120 and 140. Each day there were several bloody bowel movements. Nausea and vomiting occurred frequently although the vomitus contained no blood. Abdominal pain became severe and constant and fresh purpuric spots appeared upon the legs and abdomen. The patient passed into a state of coma and died on the tenth day after entrance. No autopsy was permitted.

178 State Street.

PRINTED INSTRUCTIONS FOR CLINIC PATIENTS

By WILLIAM HILLS SHELDON, M.D.,

NEW YORK,

CHIEF OF MEDICAL CLINIC, OUT-PATIENT DEPARTMENT, AND INSTRUCTOR IN MEDICINE, CORNELL UNIVERSITY MEDICAL COLLEGE.

That a hygienic régime is very often the most important benefit obtained from visiting a physician can, I think, be reasonably granted. Yet, since I have been connected with dispensaries I have been impressed by the lack of any intelligent idea on the part of the patient as to what he should or should not do. As an instance, I recall a man who had a serious heart lesion and who had been through repeated attacks of failing compensation. He had been told he should not overexercise and should be careful of his diet, without any more specific directions. Lifting, running up stairs, etc., did not seem overexertion to a man who had always been a truckman; neither did corned beef and cabbage, pies, etc., appear to him to be the cause of his indigestion and its consequent strain upon the heart. During all his attacks no one had had the time to explain in detail what he should do. Even if it had been explained, it is doubtful whether he would have remembered more than a small part. The examples of this sort are to numerous to mention.

Patients with chronic nephritis who have attended dispensaries for years generally have but a vague conception of their proper diet. Chronic constipation cases are given drugs with no effort at instruction. I know of a man with the latter complaint who for fifteen years had been regularly visiting clinics with no relief except from drugs, who was cured by following our printed instructions, much to his relief and our satisfaction.

I think instructions are neglected, not only in our clinics, but also in our hospitals, largely because of lack of time. Let him who thinks it does not take time sit down and labor with a patient with heart disease, taking up in detail his diet, bathing, exercise, etc. It takes an extraordinary amount of time and is a discouraging task inasmuch as on the next visit the doctor finds that the patient has not remembered more than a fraction of what has been told him, and the process of explanation has to be repeated. Is it any wonder that, with the crowds of patients and the lack of sufficient assistants, the doctor becomes discouraged, writes his prescription, and lets it go at that?

Constant verbal repetition is without doubt the best method of instruction. In the Boston dispensaries, where the doctor can frequently devote an hour to every new patient, wonders are achieved in the education of the sick poor, but here in New York, with an enormously increased number of patients and somewhat decreased number of doctors, the lesser sick must necessarily receive less time in order that proper attention may be given to those seriously ill. Under these circumstances repeated verbal instructions are out of the question in most instances.

Printed Instructions.—During the past year, in order to get over this difficulty, there have been distributed in the out-patient department of Cornell University Medical Clinic the following printed slips:

(No. 1.)

Directions for Patients with Kidney Disease.

Remember, with good care and by obeying instructions you may live many years with little discomfort.

Instructions.

I. *To avoid taking cold.*—(1) Wear flannel underclothes all the year, warmer in winter. (2) Keep the feet dry, wear warm socks. (3) Do not get wet or chilled. (4) Keep in the open air and sunshine all you can. (5) Keep your rooms at an even temperature, not too hot.

II. *To relieve the work of the kidneys.*—(1) Take a hot sponge bath every night at bedtime to keep open the pores of the skin. (2) Keep the bowels open; have at least one good passage every morning.

III. *Occupation.*—(1) Get work in which you never have to lift or strain, such as tailoring, operating, etc. It is harmful to lift heavy weights, walk too fast, stoop or climb long stairs. Rest as much as possible with not less than eight hours sleep. Do not worry or get too tired.

IV. *Diet.—Dairy foods.* Milk, cream, butter, and a small amount of cheese. *Cereals.* Rice hominy, Indian meal, barley, cracked wheat, oatmeal, cream of wheat, etc. *Breads.* Whole wheat, graham, rye, corn bread. *Vegetables.* Potatoes, beets, carrots, onions, turnips, squash, lettuce, spinach, tomatoes, peas. *Fruits.* All the fresh fruits except bananas. *Liquids.* Drink no alcoholic liquors of any kind,

not even beer. They are all absolutely poisonous to anyone with kidney disease, and are likely to cause dropsy, shortness of breath, or convulsions, and destroy your eyesight, besides shortening your life. Do not drink large quantities of water or other liquids.

Avoid all red meats, and eat eggs only in moderate quantities. *Avoid* all salted or dried or canned meats and vegetables.

(No. 2.)

Rules for General Care of Health.

1. Remember that rooms that have no sunshine are not healthy.
2. Sleep with your windows open and spend as much time as possible in the open air.
3. Take a tepid sponge bath every day, and at least two warm baths a week. Brush the teeth every morning.
4. Unless you have outdoor work, walk at least four miles every day. Practice breathing exercises and take fifteen minutes exercise daily with light dumb-bells or a cane.
5. *Habits.*—Sleep eight hours every night; be sure to have one good movement of the bowels every morning; do not drink more than one cup of tea or coffee a day; use tobacco in moderate quantities only; drink no liquor of any kind. It destroys digestion, ruins the kidneys, and leads to dropsy and other serious diseases.

Meals.—Eat moderate quantities, chew your food well. Rest for half an hour after each meal.

Diet.—Dairy products. Milk, cream, butter, and cheese. *Cereals.* Oatmeal, hominy, rice, Indian meal, etc. *Eggs.* In any form except fried. *Fish.* Any fresh fish, boiled, baked, or broiled. *Meat.* All the red and white meats, boiled, broiled, or roasted. *Vegetables.* Potatoes, beans, peas, carrots, beets, turnips, squash, lettuce, tomatoes, spinach, onions. *Fruits.* All the fresh fruits except bananas.

Avoid all fried foods, fresh breads, canned or salted meats. Do not eat pickles, pastries, or candies.

Remember, that all alcoholic liquors, including beer, are poisonous. *Do not drink.*

(No. 3.)

Directions for Persons with Heart Disease.

Remember, with good care and by obeying instructions you may live many years with little discomfort.

Instructions.

1. Hurry, worry, hard work, drinking too much liquor of any kind, or beer, will shorten your life.
2. Get work where you never have to lift or strain, such as tailoring, operating machines, etc.
3. Live on the ground or first floor, as climbing stairs is very harmful.
4. Never hurry. Do everything slowly. Don't run or walk fast. If you get short of breath, or feel dizzy or faint, stop and rest. Don't walk against a strong wind or when it is very cold.
5. Never indulge in sexual intercourse oftener than once a month.
6. Rest all you can, lie down as much as possible. Have at least eight hours sleep every night.
7. Be sure to get plenty of fresh air. Keep your windows open at night.
8. Wear flannels the year round, warmer in winter.
9. Avoid getting your feet wet.
10. See that you have one free passage of the bowels every morning, and never strain at stools.
11. Indigestion is very bad for persons with heart disease, as it is a strain on the heart. So eat very slowly, and chew your food well. Rest after meals. Do not eat so much that you gain weight.
12. *Diet.—Meat.* Boiled, broiled, or roasted meat once a day. *Dairy products.* Milk, cream, and butter in moderation. *Cereals.* Rice, hominy, Indian meal, barley, cracked wheat, oatmeal, cream of wheat, etc. *Bread, at least a day old*, whole wheat, rye, graham, corn bread. *Eggs.* Cooked in any way except *fried*. *Vegetables.* Potatoes in small quantities, beets, carrots, squash, lettuce, spinach, tomatoes, peas.

Avoid canned, salted, or fried meats. It is better to eat small meals frequently than too much at one time.

Do not drink much water or fluid of any kind at one time; it overloads the stomach and strains the heart. Drink water several times between meals, not with meals, and do not take more than a tumblerful at one time.

What to Do for Constipation.

1. Eat slowly; chew the food well.
2. Drink plenty of water; a tumblerful before each meal, and more on rising and on going to bed.
3. Keep a regular time for going to stool each morning.
4. Exercise in the open air as much as possible. Practice exercises that will strengthen the muscles of the abdomen.
5. *Diet.*—The following foods are especially useful; Apples, oranges, pineapple, prunes, figs, dried stewed peaches, cabbage, onions, spinach, "greens," tomatoes, rhubarb, butter, olive oil, coarse graham bread, rye bread, oatmeal, wheaten grits. Molasses, honey, and gingerbread are useful for children. Foods to be avoided because they cause constipation are: Milk, cheese, eggs, sweets, pastry, pickles, fried foods, and tea. It's better to eat fruits, green vegetables, and coarse cereals than much meat.
6. It is better to cure constipation by careful dieting than to be always taking pills or medicine.

We have also given out a dietary containing a list of cheap, nourishing foods, with directions for cooking them properly.

For consumptives, through the courtesy of the Board of Health, we have distributed a limited number of their pamphlets.

Satisfactory Results.—These leaflets have been exceedingly satisfactory both to patients and to doctors. Less time has been consumed and on the part of the patient more intelligent cooperation has been obtained. That the patients study these leaflets is shown by the questions asked at succeeding visits, and I have known not a few patients who could recite the directions by rote.

The expense of printing large numbers of these pamphlets is but trifling, the results most encouraging. I am well aware that the idea of these circulars is not new, and in presenting them I merely wish to draw attention to the great necessity of such forms of printed instructions, and to urge the adoption of similar leaflets by other clinics.

784 Park Avenue.

Intestinal Invagination in Children.—Kirmisson gives the symptoms of invagination as pain, colic, suppression of stools and passage of blood mixed with mucus from the bowel. The blood is the most characteristic sign. Examination by rectum combined with abdominal palpation will reveal a soft, movable tumor. The diagnosis should not be hard, since this is a disease of infancy and of strong, healthy children. It is produced by spasm of the intestine pushing one portion of the bowel into another. As soon as the diagnosis has been made a large injection under ether may be tried, and if this fails an immediate operation should be done before gangrene or septicemia has set in.—*Le Bulletin Médical.*

Signs of Organic Lesions in Epilepsy.—Francesco Agosti says that it is coming to be acknowledged that epilepsy is not a functional disease but one that is the result of pathological processes in the cerebrum. The author enumerates the signs of involvement of the cerebral system that are to be looked for in cases of epilepsy; among them are the Babinski sign, lessening of muscular power, muscular hypotonia, Neri's sign, the position of the lids, of the palate, phenomena connected with the hands, the gait, etc. The special morbid reflexes are of diagnostic value. Most of these phenomena belong to groups of associated movements which accompany voluntary movements. The author has made a study of thirty cases of epilepsy. He concludes that there are cases of epilepsy in which the signs of local organic lesions are evident, and there are other cases in which they are lacking. This absence of such signs may be due to the fact that the existing lesion is still so slight as to cause no symptoms. The author believes that idiopathic epilepsy is due to cerebral changes, alterations of the nervous elements, cellular and fibrous, and that they are the expression of a special alteration of development, causing changes in the cortex cerebri or histological and physicochemical changes in the nerve elements.—*Il Policlinico.*

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

New York, November 11, 1911.

SOME OF THE MEDICAL ASPECTS OF IMMIGRATION.

AT first thought the relationship existing between medicine and immigration may not be apparent, but a close study of the subject reveals the fact that almost all the problems of this vexed question are in their ultimate factors essentially medical ones and require the cooperation and judgment of our profession for their proper solution. The general physical and mental examination of arriving aliens, conducted with a view of sorting out the individually unfit, is undertaken by physicians of the Public Health and Marine-Hospital Service, and the general principles by which the examiners are guided are set forth in an article by Dr. J. G. Wilson, on "Diagnosis by Inspection," in the *New York Medical Journal* for July 8, 1911. Referring to the immigrant, he states that "all symptoms must have their relative value interpreted with due regard to the racial characteristics of those who present them." This principle is illustrated by noting the differences existing in various races in the mental reaction or attitude to the medical inspection itself. Thus, "the stolidity and apparent indifference of the Slav would be suggestive of melancholia if presented by the South Italian or Russian Hebrew. If the Englishman should evince the external signs of emotion which the Assyrian or Italian shows on slight provocation, his sanity would at once be in question."

This suggests that the medical inspection of immigrants not only offers the opportunity to weed out the *individually* unfit, but likewise presents a rich field for the investigation of the broad problems of *racial* unfitness. It is well known that disease has often played an important part not only in molding the physical type, but also in determining the mental characteristics of a race. Thus, the flabby muscles, apathetic countenances, and arrested physical and sexual development so common among Greek immigrants is probably due to the chronic malaria with which that nation is afflicted. Alcoholic psychoses seem to be more prevalent among the Irish than any other race. The question naturally arises as to just what part alcohol has played in the development of national mental characteristics. Among immigrants from southern Europe, where wine drinking is universal, we find no such percentage of alcoholic psychoses. Kirby found only 5 per cent. of 120 insane Italians attributable to this cause. The Jews make the best showing of all, only 0.6 per cent. of 455 admissions from this people being classified among the alcoholic insanities. Inherent racial susceptibilities to particular affections might be illustrated in many other ways. For instance, Assyrians are more liable to trachoma than are Irish peasants, though the crowding in close quarters and unhygienic surroundings which are supposed to be such prime factors in etiology of this disease are as prominent conditions in the life of Ireland as in that of Assyria. The Jewish immigrant presents the largest number of hernias and the fewest congenital deformities, and though practically free from the alcoholic psychoses he seems to be especially liable to the insanities of adolescence.

So, in like manner we might go on almost indefinitely, pointing out peculiarities of racial susceptibilities and immunities, which so far have been simply accepted as unexplained phenomena in the field of medicine, but which are no doubt governed by definite natural laws. The opportunity which our large immigration affords for the investigation of such problems should not be neglected, for such an opportunity is not likely to recur.

MODERN THEORIES OF CRIMINALITY.

ALTHOUGH America has led the way in putting into practice the most advanced ideas in penology, this country is still far behind Europe in contributing to the science of criminology. Our jurists and lawyers particularly have been slow to accept the teachings of anthropology, medicine, psychology, and the various social sciences with regard to the delinquent individual. But recent years have beheld a gradual awakening and the bench and bar are no longer subservient to obsolete traditions. They are willing to be guided by every important discovery as to the essential nature of criminality. The American Institute of Criminal Law and Criminology was established a few years ago and in order to promote the study of criminal science in this country it has secured the translation of the most important works on this subject that have appeared in the European tongues.

One of these works which is now available for English readers is from the pen of Senor de Quirós,* the eminent Spanish student of criminology. It presents a concise survey of the development of this subject during the past century. An offshoot of psychiatry, criminal science is traced back to its occult origins in demonology, and the pseudo-sciences of physiognomy and phrenology are shown to be the precursors of Lombroso's criminal anthropology. The theory of degeneration found its greatest exponent in Morel, while the Englishman Pritchard was the first to employ the phrase "moral insanity." There are three names that stand out prominently in the history of criminal science: Cesare Lombroso, Enrico Ferri, and Raffaelle Garofalo. The first reduced the etiology of

*"Modern Theories of Criminality," by C. Bernaldo de Quirós. Translated from the Spanish by Alfonso de Salvio, Ph.D. With an Introduction by Wm. M. Smithies, Esq. Boston: Little, Brown and Company, 1911.

crime to three principal factors—atavism, moral insanity, and epilepsy; Ferri showed that crime is a phenomenon of complex origin and the result of biological, physical, and social conditions; Garofalo advanced the theory of "natural crime," the crime common to all peoples, as distinguished from "artificial" or "positive" crime, which is peculiar to each nation. In addition to these main currents of thought there are subordinate theories. Among these may be mentioned Marro's conception of crime as the result of nutritional defects in the nervous system; Bonfigli's theory of developmental defects in the inhibitory centers; Benedikt's reduction of crime to a neurasthenic basis; Vaccaro's hypothesis of crime as indicating a lack of adaptation of the individual to social environment, and Nordau's definition of crime as human parasitism. The social must be distinguished from the socialistic theories which found their leading exponent in Enrico Ferri. If crime was due in most instances to social causes and influences, then, according to Ferri, the advent of socialism would mean the disappearance of the greater part of crime.

The rise of the modern systems of penology represents the practical application of the scientific study of criminality. The development of penology has shown three distinct tendencies: first, the traditional infliction of punishment as a retribution for crime without any other aim; second, the reform movement which has advocated a double aim, the repression of certain delinquents, and in others the institution of preventive measures against relapse and imitation; third, the tendency of a small minority who would consider only the preventive side of penology.

It is gratifying to note that America has taken the lead in applying the principles of modern penology. The establishment of juvenile courts and the treatment of the young delinquent not by imprisonment, but by surveillance in a reformatory or charitable institution, and the probation system are distinctively American contributions to penology. The Elmira Reformatory is pointed out as the archetype of all penal institutions. Space will not permit a discussion of the various arguments relative to the merits of the conditional and indeterminate sentence, the latter of which has been adopted in several of the States in this country. The most pithy utterance on this subject and one which sums up an entire doctrine on the treatment of criminals is that which is attributed to Griffiths, the general inspector of English prisons, who classified the criminals of all countries in two large groups: those who should never enter a prison and those who should never leave it.

One of the outgrowths of the study of the criminal types has been the development of scientific methods for the detection of crime by means of anthropometry and dactyloscopy. But the ingenuity of the criminal has enabled him to adapt himself to the arts of his pursuers. Ottolenghi has pointed out in illustration of this fact that the Bertillon system led professional criminals to abandon tattooing, while dactyloscopy makes them commit crime with gloves on in order to avoid the betraying dactylogram.

THREATENED STATE INSURANCE IN NEW JERSEY.

State insurance seems to be in the air. In Germany a system of state insurance has been in effect for some little time and in Great Britain a somewhat similar system may be adopted soon. Governor Woodrow Wilson of New Jersey has excited a considerable amount of criticism at the hands of insurance officials in this country by his statement that it may be considered necessary in the interests of the public to establish a system of state insurance in New Jersey. At the annual meeting of the Liability Insurance Association held in this city on October 19 Governor Wilson's suggestion was for the most part adversely discussed. Mr. Edwin S. Lott, president of the U. S. Casualty Company, was the chief spokesman for the opponents of the proposed scheme. Lott questioned the Governor's knowledge with regard to insurance matters and showed from his point of view that the idea in certain quarters prevalent that the rates of liability companies are too high was not correct. Against the contention that state insurance in Germany with respect to workmen's compensations for accidents had been successful the authority of Dr. Ferdinand Friedensburg, president of the Senate of the Imperial Insurance Office of the German Empire, was brought forward to demonstrate that numerous abuses had been the outcome of state control. The eminent German said that charity had crept in and corrupted the system from the beginning. The insurance office was overburdened with frivolous and unfounded claims. Officials had multiplied. The number of accidents had grown with monstrous speed. As a result of the cost of insurance, which gradually had become appalling, German industry had been put to great disadvantage and it had caused a marked rise in prices, which made the cost of living oppressive to all classes.

On the other hand Mr. S. H. Wolfe, a consulting actuary, told the meeting that in his opinion state action of some kind was bound to come and that insurance officials had better resign themselves to the inevitable. "We should be fooling ourselves," said he, "did we not come to the conclusion that before long we shall find upon the statute books of every State some law dealing with the question of workingmen's compensation, and that the treatment will be along the lines of the enactments to be found at the present time in European countries."

It appears from well authenticated accounts that the working of the German national insurance bill has injuriously affected the medical profession of that country. It likewise seems that the passage of the Great Britain bill in its present form will even more seriously affect the British medical profession. If the bill, as it now stands, is carried through Parliament it will mean that not only will medical men be underpaid but that they will virtually lose their independence and be subjected to the control of the "approved societies." The treatment which British medical men have received from societies does not lead them to favor the amplification of the system into a national affair. Moreover,

the experience of the German medical profession with their national insurance bill has been so disappointing that its members have been compelled to band themselves together into a league to protect their rights and to preserve to some extent their independence and self respect. The suggestion of the Governor of New Jersey reads as if the introduction of the thin edge of the wedge, so far as state insurance is concerned, may be near. It therefore behooves the medical profession of this country to be on its guard.

Antitryptic Index.

As was surmised at the outset, the increase of the antitryptic index in the blood serum appears with added experience to be of the same type as the diazo reaction. That is, it pertains to no one disease or class of diseases, but has in general an unfavorable prognostic significance. Katzenbogen (*Berliner klinische Wochenschrift,* October 9) concludes that an increased index corresponds to a certain amount of destruction of the leucocytes, from which we infer that in some respects it is a phenomenon the opposite of leucocytosis. The increase in the index may denote a destructive lesion of the pancreas, or the presence of placental or cancer enzymes in the blood. We cannot, however, postulate the existence of a cancer if all other evidence is negative. Of much greater significance is the presence of a normal index, for this nearly excludes malignant disease. A tumor with normal index is almost surely benign. In a highly febrile septic puerperium an increased index, if persistent, is of grave prognosis. If after a temporary increase the index subsides somewhat the prognosis becomes favorable.

Treatment of Pleurisy.

The manner in which indications of necessity may become evolved into indications of choice is well seen in the treatment of pleurisy as advocated by Arnsperger before the recent session of the Deutsche Naturforscher und Aerzte (*Deutsche medizinische Wochenschrift,* October 12). This writer advocates immediate puncture in all serous and serofibrinous pleurisies, with evacuation of the exudate and subsequent insufflation of 300 to 400 c.c. of nitrogen gas. At the same time autoserotherapy is carried out. The *x*-ray is used first, to determine the amount and seat of exudate, and after the evacuation of the latter to locate the nitrogen. At a still later period it is employed for detecting the formation of thickened areas of pleura and adhesions. If the nitrogen insufflation has been carried out successfully the latter should be at a minimum.

News of the Week.

Vital Statistics of New York City.—During the last week in October the death rate for this city was 12.2 per 1,000 population, a decrease of 1.41 points from the corresponding period of last year. The rate for the last week in October, 1898, the year the boroughs were consolidated, was 15.99, and two years later it ran up to 16.16, so that the rate in eleven years has fallen practically four full units. The decrease in mortality has been brought about in practically all diseases, the greatest decrease, however, occurring in diseases of children. The death rate among them has fallen 50 per cent. The mortality rate from infectious diseases, such as scarlet fever, diphtheria, croup, whooping cough, typhoid fever, and pulmonary tuberculosis, has also decreased for the entire city; the death rate from heart disease and Bright's disease was also considerably below the average. Queens Borough is the healthiest part of the city map, the rate being only 8.40 per 1,000, the lowest any of the boroughs has ever shown.

The Typhoid Mortality.—The Census Bureau in Washington has recently published the typhoid death rate for several of the larger cities in the registration district of the country, based upon the estimated mid-year population in 1910 for each city. The largest number of deaths, 556, occurred in New York City, although its rate was but 11.6. The smallest number, 32, is credited to Cincinnati, which also showed the lowest rate, 8.8, of all the 17 cities concerned. Second in point of number is Chicago with 300 and a rate of 13.7. Philadelphia held third place with 272 deaths, the rate being 17.5. Next came Baltimore, 235 deaths, rate, 42, the second highest of all. Then followed Milwaukee, with 172 deaths, rate 45.7, the highest shown; after which Detroit, 108 deaths, rate 23; St. Louis, 103 deaths, rate 14.9; Buffalo, 87 deaths, rate 20.4; Washington, D. C., 77 deaths, rate 23.2, the other cities showing a still smaller number of deaths with rates ranging from 13.1 to 13.7.

A Surgeon as Princeton's President.—Dr. John M. T. Finney of Johns Hopkins Hospital, Baltimore, is spoken of as the possible choice of the trustees for president of Princeton College to succeed Governor Woodrow Wilson. Dr. Finney is a graduate of Princeton in the class of 1884. His medical degree was obtained from the the Harvard Medical School in 1889.

The Nobel Prize for Mme. Curie.—The Nobel prize for chemistry has been a second time awarded to Mme. Curie. She and her late husband received the prize together in 1903 after their discovery of radium.

A Tribute to Dr. Finlay.—At a meeting of the Academy of Sciences in Havana, on October 13, Dr. Juan Guitereras delivered an oration on the life and work of Dr. Carlos Finlay. At the conclusion of the address Dr. Santos Fernandez spoke briefly on the same theme and urged the erection of a monument to Finlay in the Havana Morro, at the base of which should be engraved: "Columbus, indeed, discovered Cuba, but Finlay, by his conception, made it habitable."

The New York Physicians' Association held their regular meeting October 26. The paper of the evening was read by Dr. Charles E. De M. Sajous of Philadelphia. The title was "The Thyro-Parathyroid Secretion as Wright's Opsonin," and was discussed by Drs. Wm. Hanna Thomson, Joseph Fraenkel, Wm. N. Berkeley, and Dr. Heinrich Stern. The following cases were reported: "Chondrodystrophy in an Infant," by Dr. G. D. Scott; "Pemphigus in a Young Girl," by Dr. Gotthiel; "A Case of Intestinal Crisis," by Dr. Harry G. Watson; "A Specimen of Sarcoma of the Small Intestine," by Dr. A. Sturmdorf."

Automobile Accidents in Massachusetts.—The Massachusetts Highway Commission reports that there were 1,357 automobile accidents in the State during the ten months of the present year, in which 1,100 persons were injured and nearly 100 killed.

During the year 1910 there were 77 deaths and 963 injuries caused by motor vehicles.

The Health Department Takes Milk Stations.—The announcement is made that on November 1 the Board of Health assumed charge of twenty-two Infants' Milk Stations formerly kept by the New York Milk Committee, but about to be discontinued. These stations have nearly 4,000 babies under continual supervision.

Dangerous Hunters.—Thus far in the present year, according to the statistics of the United States Biological Survey, forty-seven men have been killed by hunters who mistook them for deer. Of these forty-seven the laragest number were reported from Michigan, with fifteen deaths, New York coming second with nine and Washington and New Jersey being tied for third place with three fatalities each.

A Hospital to Be Sold at Auction.—The court has decided that the Hempstead, L. I., Hospital must be sold at public auction to satisfy mortgages amounting to over $31,000 held by Mrs. O. H. P. Belmont. The mortgages fell due last January, and as they were not paid Mrs. Belmont instituted foreclosure proceedings.

The Crocker Cancer Research Fund.—The suit brought in the Supreme Court by the three stepchildren of the late George Crocker to get possession of the house which was left by Mr. Crocker's will to Columbia to establish a cancer research fund has been settled. The plaintiffs will get $60,000. The property is valued at $1,000,000 and the bequest to Columbia included the contents of the house.

American Association for Study and Prevention of Infant Mortality.—The second annual meeting of this society will be held at the Hotel La Salle, Chicago, November 16-18, 1911, under the presidency of Prof. Charles Richmond Henderson of Chicago. There will be six sections, the meetings of which will be held in the forenoons, the afternoons being filled by general meetings, at which the conclusions and resolutions adopted at the section meetings will be discussed by the general body.

New York and New England Association of Railway Surgeons.—The twenty-first annual meeting of this society will be held at the Hotel Astor, New York City, on November 16 and 17, 1911, under the presidency of Dr. F. A. Goodwin of Binghamton, N. Y. The corresponding secretary is Dr. George Chaffee, 338 Forty-seventh street, Brooklyn, N. Y.

Removal.—Dr. Morris J. Clurman has removed to 949 Avenue St. John, Borough of the Bronx.

Bequests to Hospitals.—By the will of the late Elizabeth K. Steele of Philadelphia the sum of $10,000 is bequeathed to the Presbyterian Hospital for the endowment of two free beds; also the sum of $5,000 is bequeathed to the Home of the Merciful Savior for Crippled Children. The following residuary bequests are made: to the Franklin Reformatory Home for Inebriates, $5,000; to the Orthopedic Hospital, $1,000; to St. Joseph's Hospital, the Jewish Hospital, and Mt. Sinai Hospital, each $500.

The Strafford County (N. H.) and District Medical Society held its one hundred and fourth annual meeting in Dover on October 26. The following officers were elected for 1911 and 1912: *President*, Harry O. Chesley; *Vice-President*, F. L. Keay of Rochester; *Secretary*, Louis W. Flanders; *Treasurer*, A. N. Smith; *Auditor*, M. B. Sullivan; *Censor*, E. C. Batchelder; *Delegate to the New Hampshire State Medical Meeting*, R. G. Batchelder.

Obituary Notes.—Dr. George Cornell Freeborn died at his home in this city on October 30. He was born in New York in 1849, studied at the school of mines at Columbia, and then for a short period entered business. His interests, however, led him to study medicine and he was graduated from the College of Physicians and Surgeons in 1873. For seven years he served as a surgeon to St. Michael's Hospital in Newark, N. J. Then becoming interested in scientific work he returned to Columbia as a teacher of normal histology, a place which he held for more than twenty years. In addition he was for a long time pathologist to the Woman's Hospital and of late years assistant pathologist to St. Luke's Hospital.

Dr. Alexander Hugh Ferguson of Chicago died at his home in that city on October 20. He was born in Ontario in 1853 and was graduated in medicine from the medical department of Trinity University, Toronto, in 1881. He removed to Chicago in 1894. He was professor of clinical surgery in the Chicago Post-Graduate School and Hospital, and attending surgeon to the Cook County Hospital. In 1910 he was elected president of the Chicago Medical Society.

Dr. Ward H. Long of Baltimore died in that city on October 23 of apoplexy, at the age of 34 years. He was born in Fort Covington, N. Y., and was a graduate of the Baltimore Medical College in the class of 1907.

Dr. Lee Smith of Bloomington, Ill., died at his home in that city on October 16, aged 80 years. He was a graduate of Rush Medical College, Chicago, in 1854. He was a surgeon in the Union Army during the Civil War, retiring with the rank of captain.

Dr. Robert L. Burrage, medical director of the Prudential Insurance Company, died at his home, Orange, N. J., of valvular heart disease. He was 54 years old and was graduated from Bellevue Hospital Medical College in 1878. He is survived by his wife and one son.

Dr. G. W. Crouse died at Citronelle, Ala., on October 13, aged 65 years. He was for thirty-seven years a practitioner in Waterloo, Iowa, and served a term as president of the Iowa State Medical Association. Five years ago he moved to Citronelle in the hope of overcoming the tuberculosis from which he suffered.

Dr. L. D. Archinard, a well-known dentist of New Orleans, was killed by a trolley car on October 12. He was a graduate of the Baltimore College of Dentistry in 1891, and was professor of operative dentistry and dental pathology and therapeutics in Tulane University.

Dr. John S. Beck of Dayton, Ohio, died of apoplexy at his home in that city on October 19. He was born in 1842 and was graduated from the medical department of the University of Pennsylvania in 1868. He was physician to St. Elizabeth's and to the Miami Valley Hospital, and was a member of the American Medical Association, the Mississippi Valley Medical Association, and the Ohio State Medical Society.

Dr. David A. Thompson of Elizabethtown, Ind., died suddenly on October 17. He was born in 1844 and was graduated from the Medical College of Ohio, in Cincinnati, in the class of 1868. He had practised in Elizabethtown for thirty-five years.

Dr. Walter R. Wilson of Hoopestown, Ill., died at his home in that city on October 19. He was a graduate of the Hahnemann Medical College, Chicago, in 1876. He served a term as mayor of Hoopestown.

Dr. A. J. Franklin of Blue Earth, Minn., died of apoplexy at his home in that city on October 13. He was born in Wisconsin in 1852 and was graduated from the College of Physicians and Surgeons, Keokuk, Iowa, in 1876.

Dr. E. P. Turner, formerly a practitioner in New York City, died of pneumonia in Stratton, Me., on October 20. He was a graduate of the Long Island College Hospital in the class of 1882.

Dr. William Nye Swift died at his home in New Bedford, Mass., on October 27. He was born in 1854 and was graduated from Harvard University in arts in 1877 and in medicine in 1881. From 1882 to 1896 he was city physician in New Bedford. He was president and one of the charter members of the medical staff of St. Luke's Hospital in that city.

Dr. George S. Albee of Worcester, Mass., died October 18 at the age of 81 years. He was born in Westmorland, N. H., and was graduated from the Jefferson Medical College, Philadelphia. He practised for many years in Hopkinton, removing to Worcester about ten years ago.

Dr. John C. Hoye of Newcastle, Pa., died in this city on November 3 as the result of an assault by some unknown person the night before. He had just come to New York to take a course of post-graduate study. He was 45 years old and was a graduate of the Medical Department of the Western Reserve University, Cleveland, in the class of 1888.

Dr. John J. Martin of Beverly, Mass., died October 28 at the age of 50 years. He was born in Lowell and was graduated from the Dartmouth Medical School in 1891. He practised for a time in Marblehead but moved to Beverly about fifteen years ago. He was chairman of the Board of Health.

Dr. Wooten Moore Wilkerson of Montgomery, Ala., died October 19 at the age of 54 years. He was born in Marion and was graduated from the University of Virginia in 1879 and from the N. Y. University Medical College in 1880. He was an ex-president of the Alabama State Medical Society.

Dr. John Bradley Crandall of Sterling, Ill., died on October 18. He was born in Roxbury, Mass., in 1840, and was graduated from the Medical Department of the University of Vermont in 1862. He served as surgeon of volunteers during the Civil War and at the close of the war entered the medical corps of the regular army. In 1868 he resigned and began practice in Sterling, where he resided continuously until his death.

Dr. Charles Fredigke of Chicago died October 22, at the age of 73 years. He was born in Carrel, Germany, and came to this country in 1857. He was graduated in medicine from the College of Physicians and Surgeons, Chicago, in the class of 1887.

Dr. George McLain of Excelsior, Minn., died October 21, at the age of 60 years. He was a graduate of McGill University in 1882, and practised for many years in Hillsboro, N. D.

Dr. Charles H. Gundelach died at his home in St. Louis on October 23, of heart disease, at the age of 74 years. He was a graduate of the Hahnemann Medical College and Hospital, Philadelphia, in the class of 1865.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

INSURANCE BILL, CONFERENCES, MEETINGS, SURPRISES—THE HARVEIAN ORATION—EVOLUTION OF MEDICAL OFFICER OF HEALTH, MEETING OF THE SOCIETY—NAVY REPORT—OBITUARY.

London, October 20, 1911.

Mr. Lloyd George has been compelled to give way to the Friendly Societies. This surprise, the last of a week of surprises, was announced late last night. The official statement issued by the Chancellor of the Exchequer gives the fact in a more roundabout way—merely intimating that the societies have accepted the promises he made in the name of the government and have "decided to invite their members to give hearty support to the bill with the promised amendments."

This news was further published in a surprising way late last night at a great meeting in the Albert Hall called by the societies to condemn the bill. There they were condemning it for two hours and a half—the representatives of three million members with a capital of fourteen millions, charged as they held to insist on their amendments. Then in the last quarter of an hour came the collapse. The chairman rose and said he had received the decision of the Chancellor to grant nine of the eleven demands of the late conference, the tenth being under consideration and for the eleventh an alternative being offered. So a resolution was passed accepting the decision, appreciating the conciliatory attitude of the Chancellor. The meeting rapidly dispersed delighted with the victory. Of course the medical profession has not the influence of these societies with their numbers, capital—and votes. But we are hoping that our interests will not be trodden upon. To take in the full meaning of the collapse—as ludicrous as many other incidents of the dispute—we need to go back only a week when the Chancellor, speaking in Whitefield's Tabernacle, denounced in his Limehouse rather than his parliamentary manner all who had dared to criticise his scheme and declared he would carry his bill this year or fall, and this determination has been repeated by government speakers throughout the week.

The adjourned conference on the bill at the Treasury was resumed on Monday and lasted over six hours. The sitting was in private and practically again adjourned. Nothing being decided platform and newspaper discussion has gone on. The doctors have been blamed in many quarters, but it is only fair to repeat that we have not given absolute opposition to the bill, though we have insisted on our manifest rights.

Our chief opposition is to the contract system unless it is put on a reasonable footing. If the state undertakes to supply attendance in sickness as a part of insurance it cannot expect us to accept terms we give as assistance to the struggling poor and we do not consider men such who can command £3 per week. From the many statements of various authorities one or two may be selected.

The London School of Economics is giving a series of lectures on state assurance. The first was by Sir. E. Brabrook who said what Friendly Societies insured against was sickness, and the smaller societies were the more successful in having fewer claims on the funds because the friendly

element prevailed. Those with less than 1,000 members had £8 per member invested, while those above 1,000 had only £4.16.0. He looked to the future with great doubt. The "wicked part" of the bill was the destruction of societies which did not "become approved" and so substituted for their own rules the "autocracy of a board." People, he held, had better manage their own affairs—even if they managed them badly.

A conference has been held by the Union of Public Health authorities respecting parts of the insurance scheme. They do not seem altogether agreed and the complexity of the plan may well cause differences. Some maintained that the existing authorities had so molded themselves to their work and had accomplished so much that it would be a calamity to hand over their duties to untried and non-elected bodies. It would be a simple matter to extend the powers of county and borough councils and give them the responsibility for administering the sick benefits, as well as for the prevention of disease which they now had. Dr. Clark of Liverpool showed that unification had been most successful in his city and was supported by several others. But some considered unification was not desirable and spoke of the great extent of the work. Others held that two committees should manage separately the health and the insurance matters.

The B. M. A. had arranged a series of meetings in various towns, and these may perhaps go on until Parliament meets unless the profession is to be treated to as unexpected a surprise as the societies. The secret sitting at the conference has naturally given rise to many rumors, but the settlement with the societies so alters the position that many are saying the doctors are now helpless. The leaders admit that some scheme of state insurance is now certain to pass and they must make the best bargain possible, especially insisting on the Chancellor making good his promises. They will hold, I hear, the general meeting on the eve of the opening of Parliament, and some say they may wait until they see how the matter proceeds in the House. Some regard this talk as a sign of surrender, but there is strong opposition to any compromise on the points which the B. M. A. has declared absolutely essential to secure the acceptance of the measure by the profession.

There are many other doctors who would gladly see the bill rejected *in toto*, and a still larger number who urge delay, as do not a few of the societies.

But the government will listen to no such thing. Having secured the support of the societies, a whip was sent out last night, saying that on Wednesday next Mr. Asquith would move that the remaining stages of the bill be guillotined and that the whole time of the House be taken by the government for the rest of the session.

The Harveian Oration at the Royal College of Physicians was delivered on Wednesday afternoon by Dr. Theodore Williams. He began by a reference to Harvey's great discovery and the results which have ensued, noticing the knowledge of tuberculosis that existed in his day and the increases that have continued to date. He mentioned that in 1852 Ancell had enumerated 54 theories put forward since Hippocrates to account for tuberculous diseases, but most of their authors attributed them to predisposing causes. The real cause, though previously suspected, was only discovered by Robert Koch. The orator then remarked that the depressing treatment common in the eighteenth century, mostly directed toward the reduction of inflammation, was the cause of the short duration of the lives of consumptives in that period, and not a difference in the type of the disease. The effects of sanatorium treatment, the substitution of graduated labor for walking exercise, the use of the several forms of tuberculin, were referred to and the orator thought it probable that most of the two-thirds reduction of the mortality of phthisis during the last fifty years was due to improved drainage, better cleanliness, and other sanitary factors. He held, too, that the dispensary system with the home visitation connected with it had proved of the greatest use, and the out-patient department of consumption hospitals ought to fulfill the same functions. Few of their cases were suited for admission to a sanatorium and the hospital was more fitted for most of the working classes who delayed coming for treatment until the late stages, though they might benefit after being in hospital for a time by removal to a sanatorium. Dr. Williams declared he was convinced that a comprehensive system of dealing with the disease should include the establishment of many consumption hospitals scattered over the country and linked with labor colonies, exchanges, and sanatoria. He said, "the task of further reducing and abolishing tuberculosis is not a hopeless one and does not lie wholly with the doctors. It lies also with those who have it in their power to reduce or remove the principal causes, viz., overcrowding, want of ventilation and open spaces, insanitary houses, lack of a good supply of water and pure milk." If all such defects were removed he believed the number of consumptives would be much smaller. The government and local authorities between them might further insist on the removal of advanced cases to hospitals or infirmaries and thus do away with one chief source of infection. If this were done "we should soon see a rapid fall in the number of contact cases and in the mortality tables."

At the annual meeting of the Society of Medical Officers of Health Professor Bostock Hill (president) gave an address in which he sketched the evolution of the officers in question, who came into existence during the nineteenth century. Though certain acts were passed by a Board of Health established between 1831 and 1848, it was in the latter year the first great public health act was enacted. But it was not until 1872 that the medical health officer was authorized to be appointed in sanitary districts, and not until 1875 that such appointments were made compulsory. Even now there are people who regard the medical health officer as a sort of superior inspector of nuisances—if not himself a nuisance. Some of the public still cling to the old idea that drains are at the bottom of all the sanitary evils that flesh is heir to, although the conception of the work of sanitation is constantly extending. One of the difficulties of getting the public to understand the work of the medical health officer, continued the president, is the simplicity of the general principles involved. Long years of superstition did not readily give way to education, which should begin in early life. So the first practical step was the advance of late years by the medical inspectors of school children. But he could not claim improved conditions as solely due to hygienic efforts as other causes reinforced them. This showed the necessity of a wider conception of the

scope of the work. He never wrote a report without a twinge of conscience on this point. In his county they had health talks by the visitors to the schools, and the teachers without exception helped forward the movement.

A blue book has been issued showing the health of the navy for 1910. The improvement is marked compared with the preceding five years. The case, invaliding, and death ratios all show a decrease and the average loss of service for each person, although slightly higher than in 1909, compares favorably with the ratio for five years. Compared with 1909, the case ratio is slightly higher, but both invaliding and death ratios show a decrease.

The death occurred on the 18th of Col. William Pleace Warburton, C.S.I., M.D., of the Indian Medical Service (retired), aged 68. He graduated at Edinburgh, M.B., 1865, M.D., 1885. After his Indian service, for which he received the C.S.I., he became superintendent of the Edinburgh Royal Infirmary.

Captain George Snyder Nickerson, R.A.M.C., M.B., Ch.B., Victoria University, governor of the Sennar Province, in the Soudan, died on October 14 in consequence of a fall from his horse two days previously. He was only 38 years old, but had been a colonel in the Egyptian army.

Dr. Horace Savory died October 13 suddenly, aged 45. He graduated at Cambridge M.A., M.B., B.C., in 1891, was late resident medical officer at Haileybury College, and wrote "Food and Meals for the Schoolboy" and various contributions to the journals.

Dr. C. V. Hitchins, medical health officer and surgeon to the Weston-Super-Mare Hospital, died on October 11 at the ripe age of 84, and was in vigorous health until quite recently. He qualified in 1854-5. He was admiralty surgeon and agent. He wrote on Weston-Super-Mare as a "Health Resort," on which he was for many years the leading authority.

Dr. John Nicholas Miller died on October 9, aged 74. Educated at University College Hospital, took the M.B Lond. 1861, and proceeded to the M.D. 1864, having previously taken the double qualification. He served his hospital as house surgeon and physician's assistant, and was for a time surgeon to the Royal Kent Dispensary. He retired from practice some years ago.

Open-Air Schools. D. Snedden.
Open-Air Rooms and Schools. T. F. Leen.
Report on Replies to a Circular Letter Concerning Fresh-Air Rooms and Outdoor Schools, Sent Out by the Associated Tuberculosis Committees of The Massachusetts Medical Society. J. B. Hawes, 2d.
Brown-Séquard Epilepsy in Guinea-Pigs. L. B. Alford.
One Hundred and Fifty-eight Cases of Heat Prostration Treated at Boston City Hospital, July 2-13, 1911. W. D. Reid.
Observations on Heat Prostations. I. C. Walker.

Open Air Schools.—D. Snedden presents the following considerations with reference to open-air schools for normal children: The restraints of the classroom expose the child to the dangers of abnormal and imperfect development. The "fresh-air" treatment of normal children would do much to prevent physical impairment of various sorts. Vigorous intellectual activity can only be carried on effectively under conditions of abundant ventilation. Open-air schools for tuberculous children are important, but vastly more important is it to get back to the sources and to stop the manufacture of tuberculous cases. Artificial ventilation seems to have been a failure. Those abnormally sensitive to cold air may by means of abundant exercise and suitable clothing avoid the development of colds. The future open-air school may necessitate the wearing of suitable protective clothing to be worn by the pupils only within the school itself.

Open Air Rooms and Schools.—T. F. Leen believes that these should be established for anemic children. If food is to be given it should be supplied by the parents, or, in cases of necessity, by private charity.

Open Air Rooms and Schools.—J. B. Hawes, 2d, presents the results of a questionnaire on this subject sent out among school officials, school physicians, and others interested in this subject.

Brown-Séquard's Epilepsy in Guinea Pigs.—L. B. Alford states that when watched in their cages the scratching reactions of so-called "epileptic" guinea-pigs are seen to be intense, prolonged, and poorly coordinated, and to occur more frequently than in normal animals. Preventing this scratching by removing its most potent exciting factor, viz., the body lice, prevents the appearance of "epilepsy" in newly operated animals and causes it to disappear in animals already "epileptic."

Heat Prostration.—W. D. Reid presents an analysis of 158 cases of heat prostration. He differentiates between three types of cases regarded from the clinical and therapeutic viewpoint: heat exhaustion, heat prostration, and heat stroke. Heat exhaustion with lowered temperature represents a sudden vasomotor palsy. On the other hand, heat stroke is thought to be a paralysis by the extreme external heat of the heat-regulating center in the medulla, with the result of the production of more heat than is given off. The heat prostration type occurs in an individual who has not been subjected long enough to severe heat or whose nervous system gives up the unequal battle earlier and before the extreme paralysis of the medullary center has occurred. In heat exhaustion there is a moist, cool skin with subnormal temperature; the pulse is small and rapid and the patient is pale and prostrated, and not rarely unconscious. Heat prostration includes the largest number of cases but has the lowest mortality. The temperature varies from normal to 103°. The circulatory condition is generally good. Heat stroke is the most serious of the three. The patients are generally unconscious, livid, and often cyanotic, with a hot, dry skin and a temperature ranging from 104° to 110°. There is venous engorgement with visible carotid pulsations, and a full, bounding pulse except in the moribund cases. The pupils are generally small, often pinpoint, and do not react to light; the knee-jerks are frequently absent, and a majority of the cases show muscular rigidity. Analysis of the author's cases shows a preponderance in males above twenty years of age. Heat stroke is more common in those past middle life. A large majority of the cases are of the brunette type. About one-fourth of the survivors require treatment of more than three days' duration. Relatively the heat stroke cases require the longest treatment. Of heat exhaustion there were 10 cases with 3 deaths; of heat prostration 87 cases with 1 death; and of heat stroke 61 cases with 38 deaths. The high mortality of the last is explained by the presence on admission of the following complications: alcoholism, failing heart, edema of the lungs, and convulsions; and later of delirium tremens, persistent coma, pneumonia, and recurrence of fever. As regards treatment, this varies with the individual case. An initial hypnotic subcutaneously is a good prophylactic against convulsions in the severe heat stroke cases. Camphor subcutaneously is a good stimulant.

Heat Prostration.—L. C. Walker presents an analysis of sixty cases of this condition.

Acute Otitis Media. G. L. Richards.
The Comparative Merits of the Various Methods Employed in Operations for Septal Spurs. J. B. Kanter.
A Statistical Review of the Work of the Tuberculosis Clinics of the Department of Health for 1910. G. H. Waters.
Dental Radiography; a Plea for Its Further Recognition. M. K. Fisher.

Osmosis and Nasal Vasomotor Phenomena.—J. Wright states that pathologically and physiologically, in the edema of inflammation and in the vasomotor nasal phenomenon, one must acknowledge the presence of a reversible mechanism, more or less delayed in the former, more or less prompt in the latter.

Vivisection.—M. J. Clurman discusses the present status of this subject.

Chronic Purulent Otitis Media.—S. M. MacCuen Smith states that the chief causative factor of this condition is the neglect or improper treatment of acute tympanic disease. In the latter streptococcic or staphylococcic infection is the most virulent. Obstructed or prevented ventilation of the tympanic cavity is one of the primary causes of aural discharge.

Acute Otitis Media.—G. L. Richards describes the treatment of this condition.

Septal Spurs.—J. B. Kanter states that the advantages of the submucous resection of the spur by the use of the chisel are the following: It avoids troublesome secondary hemorrhage by leaving no exposed cut surface of cartilage or bone. It takes very little, if any, more time than the saw operation. There is no bothersome scab and crust formation. A functioning mucous membrane is left in place of scar tissue that would result from the saw operation. There is no recurrence of the spur from thickening of the exposed cartilage or bone and scar in the mucous membrane. The wound in the mucoperichondrium heals rapidly. In five days or a week healing is complete.

Tuberculosis Clinics.—B. H. Waters presents a statistical review of the work of the tuberculosis clinics of the New York City Department of Health during 1910. He notes that the clinics are used almost exclusively by those of foreign birth. This fact seems to be due, in part, to their greater poverty and their greater willingness to accept charitable aid, in part to their greater concern for their health, but mainly to their greater confidence in and helpless reliance upon institutions of governmental character. Pulmonary tuberculosis is especially prevalent among garment workers, *i.e.* in crowded workrooms or sweat shops. When the facility and widespread extent of the dissemination of infection possible by this means are considered, it becomes an important matter, and the need of requiring disinfection of all finished clothing, as well as routine examination of all workers, might well be considered.

Dental Radiography.—M. K. Fisher emphasizes and urges upon the dental profession the wider and more frequent employment of this most safe, painless, cleanly, and accurate probe as an aid in clearing up cases of doubtful diagnosis of the teeth and accessory structures.

A Simple Method for the Treatment of Glenard's Disease.

Primary Carcinoma of Fallopian Tube.—By E. E. Montgomery. (See Medical Record, July 8, 1911, page 105.)

Typhoid Epidemic.—E. B. Bigelow reports an epidemic of typhoid fever in the city of Worcester traceable to a single milk supply, and finally to a single typhoid carrier, in whom the bacilli were found in the urine but not in the stools, and in whom the Widal reaction was positive.

The Tryptophan Test.—J. W. Weinstein has verified Warfield's findings that saliva, when not acid, is capable of decomposing glycyltryptophan into glycin and tryptophan, and these facts explain in part the reasons why the glycyltrytophan test has been the subject of such a wide difference of opinion and how it produces tryptophan when no cancer exists, which renders it so unreliable in cancer diagnosis.

Hemoptysis.—M. Rothschild recommends in cases of obstinate hemorrhage occurring in the course of pulmonary tuberculosis the production of artificial pneumothorax by means of nitrogen.

Climatic Treatment of Pulmonary Tuberculosis.—W. J. Barlow notes that the atmospheric conditions of greatest importance are in order of importance: (1) Plenty of air. (2) Percentage of sunshine. (3) Amount of humidity. (4) Temperature with its variations. (5) Pressure of air. (6) Severity of winds, dust, etc. As a general rule patients with pulmonary tuberculosis developing between the ages of seventeen and forty should be sent to a high dry altitude. With disease beginning after forty patients should be kept in lower altitudes and more equal and relaxing climates, and children will always do better near the coast in cold or warm climates. The great mass of tuberculous patients under the age of 40 in the early stages, with or without fever and constitutional symptoms, including patients with hemoptysis and those with beginning dyspepsia, present indications for high altitude treatment (3,000 to 7,000 feet). So also do cases with compensated cardiac disease and with no great degree of emphysema. Contraindications are acute pneumonic cases with high fever, rapid pulse and respiration, advanced cases with extensive involvement or cavity formation of both lungs with extensive adhesions and dyspnea, chronic fibroid cases with a good deal of bronchitis and emphysema, young children and infants, and many patients of a neurasthenic type of nervous temperament. For medium altitude treatment (1,000 to 3,000 feet) there are many resorts throughout the East which are suitable at all seasons of the year. In the West there are only two important places of this sort, Phoenix (altitude 1,087 feet) and Tucson (altitude 2,400 feet). Of these, Tucson is probably better for all-round climatic advantages, but for those who can exercise and ride around Phoenix would probably be more agreeable. The southern California resorts are all included in the low altitudes by the author as well as are those in the region of the Great Lakes and in the Southern States.

Iron in Tuberculosis.—E. S. Bullock and L. S. Peters have adopted the Italian practice of using citrate of iron

hypodermically in the secondary anemia of tuberculosis. As is generally understood, a high altitude in itself is very effective in removing the secondary anemia and it is only in specially resistant cases that they at first employed this method. The dose used is not over 0.05 gram hypodermically in the buttocks daily until some result is obtained.

Dietetic Management of Pellagra.—G. M. Niles states, that while the maize theory of the origin of pellagra has not been absolutely disproved, one should not include any substance derived from that plant in the diet of patients treated for pellagra. Flesh proteins seem to be well borne. Eggs are generally permissible. Sweet milk is valuable when it agrees, and buttermilk is a most useful article of diet and is generally recommended. When constipation exists, oatmeal, tender vegetables (in pure form), thoroughly baked potatoes, or cereals with but little sugar are suitable.

Immunity in Tuberculosis.—G. B. Webb, W. W. Williams, A. M. Forster, and G. B. Gilbert in their experiments on monkeys have not been able to determine the exact number of tubercle bacilli which will infect the rhesus monkey, nor have they been able to demonstrate any antibodies in its serum.

Anemia of Tuberculosis.—By W. J. Barlow and R. L. Cunningham. (See MEDICAL RECORD, July 8, 1911, page 92.)

Intestinal Approximation.—J. B. Bacon describes a device for intestinal approximation—consisting of a simple grooved ring three-eighths of an inch wide and three-fourths of an inch in diameter made from thin sheet silver with a forged groove one-eighth of an inch deep to hold the compressed tissue under a ligature. It simply acts as a hollow cylinder for the passage of liquids and gas, and at the same time as a base on which to tie the connective tissue by means of a rubber and silk suture of coarse fiber, and thus have a firm union for three or four days while the serosa and muscularis are becoming united by organized lymph.

Universal Gravity Outfit.—W. T. Mefford has devised an apparatus which can be used in the treatment of abscesses by the closed method, as recommended by Wright: in the treatment of hydrocele: irrigation of the bladder; proctoclysis; the intravenous administration of salt solution, defibrinated blood, salvarsan, and other medicines: the subcutaneous administration of salt solution; and for direct intravenous transfusion.

Institutional Care of Young Infants.—By T. S. Southworth. (See MEDICAL RECORD, July 1, 1911, page 49.)

Summer Heat and Diarrheal Diseases.—By I. A. Abt. (See MEDICAL RECORD, June 8, 1911, page 106.)

Twin Pregnancy in Uterus Bicornis.—P. G. Hurford reports a case of this condition, with the delivery of one living and one dead child.

Chisels for Making Bone-Flaps.—D. M. Greene describes circular blade, hollow, and guarded chisels devised by him for the purpose of avoiding the fractures which cause detachment of the periosteum in making bone-flaps.

Slip-Meniscus.—G. Chandler details the following treatment for slip-meniscus or dislocation of the internal semilunar cartilage: He uses a piece of sole leather cut in a shape to be fitted to the inner aspect of the knee-joint and about 4 inches long and 1¾ inches wide. By soaking the leather in water and whittling the edges it can be molded into shape. This is firmly fastened over the cartilage by means of adhesive straps.

Staphylococcus Spray in Diphtheria Carriers.—S. R. Catlin, L. O. Scott, and D. W. Day state that the ordinary immunizing dose of diphtheria antitoxin does not always protect an exposed individual against the disease. Only by regular and constant taking of cultures can institutional epidemics of diphtheria be controlled. The usual methods of throat antisepsis are of little value in ridding the throat of diphtheria bacilli. Treatment of the nose is as important as treatment of the throat. In institutional epidemics more than one series of three negative cultures is necessary for release. Results with the use of a broth culture of *Staphylococcus aureus* as a spray for the purpose of ridding the throats of the diphtheria bacillus, as recommended by Schiotz, were such as to warrant recommending its further use. Apparently no harm results from the application of the spray.

Transfusion of Blood.—A. H. Curtis and V. C. David describe a new method and apparatus for performing this operation.

Glenard's Disease.—G. W. McCaskey describes his application of the method of employing adhesive plaster supports in the treatment of visceroptosis.

Old and New Views on Treatment of Tuberculosis.—C. T. Williams notes that in Harvey's time the principal treatment for cases of scrofula or the king's evil was the royal touch. The first writer on tuberculosis after Harvey's time was Christopher Bennett, who proposed treatment with bleeding, cough mixtures, and inhalations. At the beginning of the eighteenth century appeared Morton's "Phthisiologia," which recommended bleeding, purging, and the administration of emetics, diuretics, diaphoretics, crab's-eyes, etc. Sydenham recommended bleeding, purging, and "long and continued journeys on horseback." Laennec considered the best means of opposing the disease was by sea voyages or residence on the sea-coast in a mild climate. In 1866 the tonic treatment of tuberculosis had commenced, chiefly with the aid of cod-liver oil, which was placed at the head of all remedies. Although the open-air and sanatorium treatment was originated in 1840 by Bodington of England, the idea developed on German soil; the first sanatorium being Brehmer's at Görbensdorf in Silesia. Here methodical hill-climbing was a part of the treatment. The object was to further the development of the heart—a small heart, according to Brehmer, being one of the predisposing causes of phthisis. Dettweiler substituted for hill-climbing the Liegehalle system, in which the patients lie for several hours together in open shelters. Walther of Nordrach advocated instead a form of solitary confinement during the rest hours, and outdoor walks in all weathers with overfeeding. According to the statistics of the modern German sanatoria, 44 per cent. male and 51 per cent. female consumptives are capable of work four or five years after leaving the sanatorium. A system of graduated labor as a substitute for walking exercises forms a prominent feature of the treatment at some of the English sanatoria. The author's statistics of the effects of high altitudes in the treatment of consumptives showed the most favorable results and the fewest relapses. There is still no unanimity of opinion as to the value of tuberculin.

Congenital Dislocation of the Hip.—G. C. E. Simpson states that congenital dislocation of the hip is a condition which progressively gets worse till puberty and may cause severe deformity. In adult life further trouble may arise and completely incapacitate the patient. Treat-

ment by manipulation at the earliest possible time after infancy may be expected to yield a stable articulation with perfect function in 60-70 per cent. of cases. A slight limp (due to imperfect growth of the bones) and some slight limitation of movement may remain, but the children are cured of any obvious deformity or incapacity. Of the remaining 35-40 per cent. the condition is usually much improved by treatment. The treatment in children below 8 years of age is attended by little or no danger and by few unfavorable accidents. The trouble caused to the parents is slight and the loss of school attendance in early childhood is of but small importance. In children between 9 and 12 years of age treatment by manipulation has greater dangers and inconveniences and gives much less favorable results. It should, however, be tried in all cases which have unfortunately reached this age with the condition unremedied; great care and gradual reduction avoid the dangers of shock and laceration and considerable improvement is usually effected. In unsuccessful and relapsed cases some form of open operation may prove of advantage.

Axial Rotation of Uterine Fibroid.—J. Bland-Sutton reports a case of this condition, in which the pedicle was twisted like a rope. The twist also included the uterus, Fallopian tubes, and ovaries.

Acute Rheumatism in Children.—F. Langmead finds that there is a large amount of disregarded rheumatism among the children of school age in London. With the knowledge that about 1 in every 15 children from the age of 7 onward attending the elementary schools is rheumatic, and that about 87 per cent. of these have some consequent affection of the heart, one may well consider what may be done to remedy this serious condition of affairs.

Acute Endocarditis.—A. T. Nankivell reports the case of a child three and a half years old in whom a mild attack of scarlet fever was complicated in the third week with an attack of endocarditis. Blood cultures showed a non-motile diplococcus hitherto undescribed.

Spinal Anesthesia.—H. E. S. Stiven states that the most notable feature with regard to operations in 1910 is the great advance which stovaine has made as a routine anesthetic. In his hospital service in Egypt the operations under stovaine exceed those under general anesthesia. The figures are: stovaine, 662; general 599. No untoward results are recorded, and the chief danger seems to be a lowering of the general blood pressure during the operation. In the majority of cases this can be remedied by the administration of adrenalin. Stovaine did not produce its customary effect in at least 16 cases, which, therefore, had to be done under a general anesthetic. Operations were finished off under chloroform in at least four cases. A successful administration of "high stovaine" was accomplished in 17 cases.

Auricular Fibrillation. J. Mackenzie.
Infusion Anesthesia. The Use of Normal Saline Infusion as a Means of Administering Ether. F. Rood.
The Symphyseal Ligament of the Parturient Guinea-Pig. J. Bland-Sutton.

Treatment of Tuberculosis.—By C. T. Williams. (To be noticed later.)

Auricular Fibrillation.—J. Mackenzie continues the discussion of this subject, noting the manner by which it may be recognized, its prognostic significance, and its treatment. Graphic records show that all signs of an auricular wave disappear from the apex beat and the jugular liver pulses, and that these pulses change at the onset of auricular fibrillation from the auricular to the ventricular form. There are frequently present small waves caused in some way by the fibrillating auricle. The electrocardiogram gives a characteristic record, the chief feature of which is a total disappearance of the peak due to the auricle. As regards the clinical characteristics, it is noted that auricular fibrillation is very frequent in two classes of cases, namely, heart disease of rheumatic origin, and that due to senile degenerative changes. The patient may first become conscious of the condition that has developed insidiously in his heart by sensations of abnormal rhythm: long pauses, that may be followed by big beats; by paroxysmal tachycardia accompanied by a gentle fluttering in the chest that may be interrupted by thumping sensations. The pulse is characteristic, of a very irregular kind; not like the irregularity in the heart of the young, or the intermittent pulse, or the irregular pulse due to extrasystoles; in auricular fibrillation, as a rule, the pauses between the beats are continually changing, and two succeeding beats are rarely of the same strength. If there is a diastolic mitral murmur without a presystolic murmur one can in the majority of cases conclude that auricular fibrillation is present. The signs of heart failure are usually the first to attract attention, are not characteristic, and vary from a slight breathlessness on exertion to dyspnea of the most severe kind accompanied by dropsy, enlarged liver, and the symptoms associated with extreme heart failure. In giving a prognosis in cases of fibrillation it is necessary to form an opinion of the changes that have led up to the fibrillation: the prognosis will depend upon the extent of these changes. A valuable aid to prognosis is obtained by noting how speedily the heart responds to digitalis. In treatment, the first measure is to ease the heart of its work. The drug *par excellence* in this condition is digitalis, used in the form of the tincture. In cases of marked failure the quantity of the latter to be administered is one dram per day in doses of 15 to 20 minims.

Infusion Anesthesia.—F. Rood presents a series of twenty-one cases in which ether was administered by intravenous infusion in a 5 per cent. solution in normal saline. This method was originated by Burckhardt. The mode of inducing anesthesia is as follows: An hour before the induction a hypodermic injection is given, which consists of scopolamine 1/100 grain, morphine, 1/6 grain, and atropine 1/100 grain. The patient is placed on the operating table and the selected arm lightly bandaged to a splint to prevent flexion of the elbow; a few drops of cocaine having been injected into the skin, the vein is exposed through an incision of a third of an inch. The cannula having been tied in, it and the wound are packed round with sterile gauze. The strictest asepsis is, of course, preserved throughout this procedure. The solution is run in rapidly during the period of induction, which usually lasts about ten minutes. It is usually possible to attain surgical anesthesia with the use of 8 ounces of the solution, while for the maintenance of the anesthesia as little as a pint an hour (1 ounce of ether) is in most cases enough. The most striking features of infusion anesthesia, the author maintains, are: (1) Extreme flexibility so that the condition of the patient can be adjusted with great nicety and can be changed in the direction of deepening or lightening of anesthesia with really remarkable rapidity. (2) The patient begins to come round very soon after the anesthetic is stopped and is able to converse rationally within a few minutes. (3) Postanesthetic vomiting and pulmonary irritation are both extremely rare.

Symphyseal Ligament in Parturient Guinea-Pig.—J. Bland-Sutton confirms what has been noted by Owen, namely, that parturition in the guinea-pig is accompanied by a marked extensibility and elongation of the symphyseal ligament.

October 16, 1911.

Treatment of Lupus with Nascent Iodine.—According to Reyn an attempt had already been made to decompose sodium iodide in the tissues through the aid of a stream of ozone topically applied. The author has sought the same end by electrolysis. After successful animal experiments, human subjects with lupus vulgaris were treated. The skin lesions in some cases had already been healed by the Finsen light, but there were patients with mucous lesions and untreated or unhealed skin lesions. The patients received one to three grams of sodium iodide per os and one hour later electrolysis up to three milliampères, 65 volts, the needles being applied *in situ*. The action on the lesions was surprisingly prompt and favorable That nascent iodine was present readily appeared from the starch test.

Treatment of Typhus with Iodine.—Uftugeaninoff has tested Jaworowsky's method of treating exanthematic typhus with iodine internally. He gave three drops of the tincture three or four times daily. Although but fourteen cases were treated, it appears that the remedy exerts a certain specific activity. That it is actually curative cannot as yet be maintained. The specificity of the action appears readily from the temperature fall, the abortive character of the exanthem, the favorable influence on the nervous system and pulse. The combined material of Jaworowsky and the author amounted to fifty-five cases, without mortality.

Action of Pressure Massage on the Nerves.—Jaffe writes with reference to the treatment of neuralgia with massage. The latter is one of a number of therapeutic resources for this affection and is believed to be especially efficacious in sciatica. The rationale is not clear, but the effects seem akin to those of nerve stretching combined with pressure. The treatment, as carried out by the special massage technique, seems at first to aggravate the condition, but improvement soon follows. It is assumed that after a preliminary hyperemia some degeneration of nerve fibers follows, to be succeeded by a regenerative process.

Hydrophthalmus Infantum.—Writing of the so-called glaucoma of childhood, Fejer states that it is a very rare affection and usually unilateral. Its nature remains obscure. He has seen three cases. In the first—in a boy of four—the trouble seemed to date from birth. The affected eye was larger and became inflamed, watery, and painful, with increased tension. The cornea was cloudy and the pupil atrophic. The eye was enucleated as there was no prospect of cure. The second case was seen in a boy of the same age, but the affection was bilateral. Attempts were made to relieve the patient with pilocarpin and anterior sclerotomy on the worse eye, but to no purpose. As both eyes were compromised enucleation was not done. The third patient was nineteen years old, affected since childhood. Some vision remained in the left eye—5/50 with a convex lens. Both eyes were improved by iridectomy, the vision of the left eye surpassing that of the right.

Indications for Artificial Termination of Pregnancy.—Runge enumerates these in the following order: Tuberculosis should first be mentioned, especially its laryngeal localization, this forming a strict indication. In pulmonary phthisis he would not interfere after the fourth month. Before that period each case should be decided for itself. Next in importance is heart disease, and here also each case must be individualized. With good compensation or even in its absence, provided the patient reacts properly to digitalis, there need not be any intervention, but labor must be made as brief and easy as possible. Diabetes and pregnancy are not often seen together. If the disease can be controlled by diet gestation need not be interrupted. Albuminuric retinitis and optic neuritis may demand artificial termination of pregnancy to prevent blindness. Other affections to be considered are mental disturbances—suicidal impulses and phobias call for intervention—chorea, chronic nephritis, pyelitis, hyperemesis, pelvic anomalies, and fixations of the uterus both spontaneous and operative.

October 17, 1911.

The Vasomotor Syndrome in Children.—Hamburger discusses this syndrome as an expression of neuropathy which stands in a certain causal relationship with arteriosclerosis in adult life. These children are often brought to the physician for palpitation of the heart. Not much is found by objective tests. The rhythm is unstable, the impulse diffused, there is epigastric pulsation and in many cases the position of the organ changes readily with that of the body. The pulse frequency also increases with rising and slight exertion and a respiratory type is then noted (increase during inspiration, decrease during expiration). Vascular symptoms are very numerous and varied. Many of these depend upon active congestions and ischemias. Headache, even migrane, is common after mental effort. Vertigo and fainting attacks are also common. Cold extremities are another expression of local ischemia. Other symptoms are dermographism, visible pulsation of the carotids, increased tension of the radial and temporal arteries, the walls of the vessels being distinctly palpable. This condition naturally shades into the so-called juvenile arteriosclerosis which some authorities regard as of common occurrence. There is naturally a complete vascular instability, which represents the predisposition (angiasthenia). Upon this predisposition a great many kinds of irritation, toxic, psychic, physical, work. Certain mental characteristics also accompany the predisposition. The children are sensitive, easily elated or depressed, often benevolent and highminded. They learn readily in school and are ambitious. These traits are no doubt due in part at least to the vasomotor instability.

Influenza Bacteriemia.—Reiss and Gins report a case of this rare condition. Its infrequency is due doubtless to want of success in cultivating Pfeiffer's or other germs from the blood. The case cited was a complete one from this point of view, and Pfeiffer's bacillus was cultivated from the blood 17 days before death. The patient was a nursling who first had measles, from which she made a good recovery. A few days later marked fever again appeared which assumed a septic type. It was at its acme at the early morning hours, sank to nearly normal in the morning, and rose again in the afternoon. Bronchial sounds were heard to the right, behind; and later they appeared on both sides toward the apices. The *x*-ray showed shadows which corresponded to areas of percussion dulness. Blood was taken for a test but thus far there had been no suspicion of influenza. The diagnosis was evidently sepsis of unknown origin. The Pirquet reaction was found to be negative. Death finally took place from cardiac weakness. The autopsy showed no evidence of pyemia, nor of any local septic condition beyond pneumonia.

Diabetes Mellitus and Adrenalinemia.—Bittorf asks if the adrenals are hyperactive in diabetes mellitus. He has recently tested the blood in ten diabetic patients with the frog pupil method. In seven cases in which there was no acidosis he found no evidence of adrenalinemia, even in one case later found to have an atrophic pancreas. Instead of a dilatation of the frog's pupil the author repeatedly saw a contraction. In the three diabetics with acidosis there was a slight or doubtful positive reaction, but the dilatation was succeeded by contraction. Because of this finding, the author says, he altogether disbelieves in the existence of hyperactivity of the adrenals in diabetes mellitus.

Deutsche medizinische Wochenschrift.

October 12 and 19, 1911.

Nature and Treatment of Eclampsia.—Zangemeister believes that puerperal eclampsia must be regarded as a sort of reflex epilepsy. Toxins he would consider rather as predisposing than exciting causes; that is to say, they do not behave like strychnine, for example, in setting up convulsions in a normal soil. The toxins, placental or other, so affect the central nervous system as to make it easily convulsible. The exciting cause is always uterine contraction, whether gestational, parturient, or postpartum. The parallel between these pains and eclamptic seizures is unmistakable. The nervous centers are believed to be anemic as a result of the toxicosis at the onset of the convulsions. The author admits without comment that eclampsia has been known to occur in ectopic pregnancy, but uterine contractions may of course be present here. The anemic state of the brain in eclampsia favors the development of cerebral edema and the author has in several desperate cases practised trephining with the aim of reducing intracranial pressure. The results were encouraging and the author hopes that he has added a new resource to the heroic measures for saving life in eclampsia.

Rhinogenous Traumatic Meningoencephalitis.—Manasse reports a case of this type in a 16-year-old girl who, while knitting in a railway carriage, had one of the needles driven into the left nasal chamber. She lay unconscious for hours. Within the next two days headache, vomiting, and purulent nasal discharge set in. The syndrome of meningitis was in evidence when patient was first seen. Lumbar puncture showed a sterile fluid. The frontal and ethmoidal simuses were at once opened and bony tissue removed until the dura was accessible. This was split along the track of the needle wound and the opening drained with iodoform gauze. Despite precautions a cerebral abscess formed, the pus from which contained the *Diplococcus lanceolatus*. The patient recovered. The author had not been hopeful of the outcome. The novelty of the case left him without precedent and he simply followed the principles which underlie the treatment of otogenous meningitis. An integral part of the management was repeated lumbar puncture.

Unusual Collateral Phenomena in Mitral Stenosis.—Muktedir Effendi refers to pulse differences in the radial arteries and paresis of the recurrent laryngeal nerve. Gouget recently reported instances of these complications and the present writer was able to confirm them from his own experience. Both patients showed the pulse differences and one of the two recurrent paresis. In typical cases of mitral stenosis examination usually fails to detect any evidence of these complications. The inequality of pulse is due probably to the strongly dilated vena cava and right innominate vein which compresses the innominate artery of that side. Recurrent paralysis is usually unilateral. The left nerve is always involved and at times both nerves. The paralysis is due doubtless to compression by the left auricle. The sympathetic nerves are involved with the same relative frequency, as shown by the pupillary symptoms. This triad—pulse inequality, recurrent paralysis, and pupillary behavior—is usually taught to be pathognomonic of aneurysm of the aorta, hence the importance of the finding in mitral stenosis.

Relations of Coprostasis to Bronchial Asthma.—Ebstein had already written on this subject but without attracting the attention of the profession. Quite recently Pinz has taken up the matter. Since a definite relationship has long been noted between stercoremia and certain dermatoses like urticaria, and since these dermatoses sometimes behave as equivalents to bronchial asthma and *vice versa*, it follows that stercoremia should be able to cause asthmatic paroxysms. That this is possible appears from the two cases which Ebstein reports in detail. This type of asthma is toxic in nature, comparable in a measure with uremic asthma. This toxic type does not appear to be very closely related either with the organic, reflex, or neuropathic types which form the greater part of all asthma cases.

Differentiation Between Aphasia and Anarthria.—Gutzmann writes at great length on this subject. While typical cases of either possess little in common, there are many instances in which the two may be associated, or in other words aphasia may possess an anarthric component. It may likewise be maintained that true disturbances of articulation exist as a result of cortical mischief. Centers in the pons and medulla oblongata preside immediately over mechanical speech, but are indebted for much of their activity to cortical influence. What is known as subcortical motor aphasia seems to be a connecting link between aphasia and anarthria, since it presents the phenomena of both the latter. Every shade of opinion as to the relationship of these two conditions seems to have been upheld, largely because of differences in individual experience. In recovered cases of aphasia mechanical speech defects sometimes persist. The present author believes that in every case of complete cortical motor aphasia there is a dysarthric component. To be able to demonstrate the presence of the latter is his special task. He has devised a system of articulation gymnastics requiring speech coördination, with graphical methods for recording which is not put forward as wholly original since Goldscheider has done work of a similar character, and many others have occupied themselves with experimental phonetics. Tracings show very clearly the differences between normal articulation and dysarthria.

Dystrophia Adiposogenitalis.—Pick begins as a serial perhaps the most extensive monographic study of this subject which has as yet been undertaken. Marie described acromegaly in 1886 and in 1901 Froehlich published an account of a condition apparently the reverse of the latter. The existence of the so-called Froehlich syndrome was promptly recognized by clinicians. Both it and the Marie syndrome are known to stand in direct relation to tumors of the hypophysis but the precise relationship is by no means obvious. The assumption that one syndrome is due to defective and the other to excessive functioning of the pituitary body may not be borne out by the facts but it seems certain that both are due to a dyspituitarism. Cases are upon record in which Froehlich's syndrome underwent improvement after successful removal of the offending tumor of the hypophysis—a type of result of more frequent occurrence in connection with acromegaly. Moreover, cases occur in which there is an association clinically of acromegaly and dystrophia adiposogenitalis. That tumors determine both hyper- and hypofunctioning of the pituitary body is evident, yet clinically the two cannot always be separated, any more than in connection with the thyroid. Atrophic alterations suggest lowered functions, hypertrophic alterations heightened functions, yet as we see in connection with the testicles and ovaries a possible sexual component comes into play; so that what is apparently an excess of growth may really signify a defect. Thus the fat deposit may be conceived as a defect in the dystrophia adiposogenitalis and the eunuch voice in acromegaly is manifestly a defect.

Malformation of Femur.—O. L. Addison reports the case of a child 2½ years of age, in whom the right leg was two inches shorter than the left. The femur was much curved, and there was a marked degree of coxa vara. The leg was first noticed to be shorter than the other when the child was 10 months old. There was no history of injury.—*Proceedings of the Royal Society of Medicine.*

Insurance Medicine.

THE AGENT AND THE APPOINTMENT OF EXAMINERS.

An agent will not infrequently promise to procure the appointment of examiner for some physician as an additional inducement to the latter to take out a policy in his company. This procedure is recognized by well-regulated companies as a very questionable one, and some of them go so far as to follow up each new appointment made at the request of an agent with a systematic search of the records to ascertain if the appointee has taken out a policy at or about the time he was made examiner. If it is found that he has done so, he is informed at once by letter that he must not consider himself indebted to the soliciting agent in any way, as the latter has absolutely no influence in the appointment of examiners other than notifying the company that a vacancy exists at some point; also, that, while the company is glad to have him on its list of policy holders, it can not extend any privileges to him on that account.

This line of action will not fail to meet the approval of all physicians, especially when their attention is directed to two points: (1) An agent who makes this proposition to one doctor will repeat it to others and will not be deterred by the fact that any of them happen to practise in the same place as the one already favored, since he has the idea firmly fixed in his mind that new business must be obtained even if his methods are not always commendable. If such nominations were approved at the home office, the position of examiner would become cheapened sooner or later and not worth seeking. It may be added that, generally speaking, urgent requests from an agent for the appointment of a certain physician are not well regarded at the home office and that efforts are made toward choosing another doctor if there is one in the same community equally equipped. (2) A company necessarily depends upon every one of its examiners for honest, fearless, and painstaking work, and the relations between the two must not be weakened under any circumstances by other obligations. The examiner must be free and independent, not bound to the agent by any sense of gratitude or indebtedness; the company, on the other hand, must not be hampered in the slightest degree by the fact that the examiner carries one of its policies.

Medical Section of the American Life Convention.—(See page 1004.)

Threatened State Insurance in New Jersey.— (See page 979.)

Anamnesis in Accident Cases.—Ruge says that careful history of the incidents preceding an accidental injury, or what is claimed to be an injury, often clears up the question of the relation between the alleged accident and the damage done. Thus a fall followed by symptoms of apoplexy may simply have been a result of the apoplexy and not its cause. A careful history of the symptoms may clear up such a case. Appendicitis is frequently claimed to have been due to a kick, a blow, etc., yet in many cases the findings at operation show a long-standing inflammation of the appendix. Traumatic tuberculosis must be proved to have started from the site of injury: usually the injury simply brings to light an existing tuberculosis. Many physicians claim indemnity, if insured, for becoming infected with such a disease as measles. It should be shown in such a case where the source of infection was probably found and whether proper measures were taken by the insured to protect himself. In discussing Ruge's paper, Böhler said that the definition of accident is an ever-changing one, because modern medicine is more and more inclined to see a causal relation between injury and disease. Insurance companies should therefore rigidly formulate certain conditions as not includable among those due to accidents. This has been done in the case of ruptures, and it should be done in cases of infectious disease among physicians. Otherwise, other professional men, teachers, for example, should be indemnified for contracting an infectious disease, like measles, in the discharge of their duties. Lennhof objected to the statement that traumatic tuberculosis originates at the site of injury. The damage may be done a good distance from this site by indirect transmission of the damaging force.—*Blätter für Vertrauensärzte der Lebensversicherung*, January and February, 1911.

Cardiac Symptoms and Life Insurance.—Grassmann says that the physical findings in reference to the heart frequently decide the fate of an applicant for insurance, so far as acceptance or refusal are concerned. The proper interpretation of cardiac findings is therefore very important for both the applicant and the insurance companies. The latest clinical and pathological studies of the circulation have introduced many new points of view and these should not be neglected by the medical examiners. Thus arrhythmia used immediately to suggest degeneration of the myocardium and the consequent dangers to the life of the patient. However, it has been shown that only the so-called "perpetual irregular pulse" always means the existence of an organic disease, for example, of a valvular lesion or of arteriosclerotic damage to the heart. On the other hand, juvenile arrhythmia has no such significance; it is usually of nervous origin and may be an hereditary condition and not a serious disease.

Arrhythmia caused by extrasystoles has frequently led to the refusal of an applicant; yet this phenomenon is not uncommonly of purely nervous nature and may be produced by excessive use of tobacco, for instance. Mackenzie says that he has never seen anything serious follow his irregularity in youthful and nervous individuals. Broadbent says that an intermittent pulse is not characteristic of any form of heart disease and but seldom points to organic disease of the heart. In older individuals this phenomenon is of ill significance when it can be shown to have appeared only recently. Valvular lesions should also not be grouped all together as very serious from a prognostic standpoint. Those following an endocardial inflammation are, of course, serious, but frequently a mitral leak may be due simply to muscular insufficiency and not to changes in the valve itself. Chlorosis and anemia of girls and young women frequently lead to such an insufficiency.

"Dilatation of the heart" has become a very fashionable diagnosis, since various mechanical methods of measuring the size of the heart have been multiplied. Yet Romberg says that such a diagnosis should be made only in the presence of undoubted and considerable increase in the size of the heart, for normal variations are likewise considerable. Variations in blood-pressure should also be very carefully interpreted; moderate increase over normal has not much significance, and, on the other hand, low blood-pressure may coexist with a marked degree of arteriosclerosis.—*Blätter der Vertrauensärzte der Lebensversicherung*. January and February, 1911.

Delicate Test for Albumin in Urine.—A. Ravold has found that the Spiegel-Jolles reagent and sulphosalicylic acid form the two best reagents for detection of albumin. The former reagent, however, seems to deteriorate with

age. For the second test, a 50 per cent. solution of sulphosalicylic acid is dissolved in distilled water and 15 drops (1 c.c.) added to five or six c.c. of urine in a tube. A white precipitate forms if a quantity of albumin is present; if the amount is small the urine becomes turbid. The precipitate or turbidity does not disappear on heating. Albumoses are also precipitated by the reagent, but disappear upon heating, to reappear on cooling.—*Proceedings of the Medical Section, American Life Convention, New Orleans,* February, 1911.

Cancer of the Testicle Following Injury.—Haberern says that the rôle of trauma in the causation of cancer is fast becoming a very important and practical problem, because of the numerous claims for indemnity for neoplasm following injury, in accident insurance. He communicates the following case. A healthy individual, 31 years of age, was kicked by a horse in the right testicle. Six weeks later there appeared a tumor of this testicle which on pathological examination proved to be adenocarcinoma. The lymphnodes in the inguinal region gave a similar picture. The patient died several months later of recurrence of the tumor and internal metastases. Haberern quotes Löwenstein's cases of testicular carcinoma following injury and considers his to be the fourth case published. Sarcoma of the testicle after a similar accident seems to have been much more frequent, over two score cases being mentioned by Löwenstein.—*Deutsche Zeitschrift für Chirurgie,* September, 1911.

Industrial Accidents and Diseases in England.—In the Annual Report of the Chief Inspector of Factories and Workshops for the year 1910 the subject of accidents again receives careful consideration. The Accidents Committee appointed in 1908 to investigate accidents in places under the Factory and Workshops Acts reported in February last. From 1897 to 1907 the accident risk apparently remained nearly constant; any slight increase due to the extended use of machinery and greater pressure of work was counteracted by improved inspection and by greater care resulting from the operation of the Workmen's Compensation Act. Since 1907 the decline in the number of accidents has been partly due to the more efficient guarding of machinery adopted by employers; but, taking the accident statistics generally, it would appear that, while there was a decrease during 1908 and 1909 owing to slackness of trade, in 1910, with the increased volume of manufacture, there came an increase. The fatal accidents for 1907, 1908, 1909, and 1910 were respectively 1,179, 1,042, 946, and 1,080, the total number of accidents being for the same years 124,325, 122,154, 117,500, and 129,550. The total number of accidents for 1910 was 4 per cent. greater than for 1907, the highest previous record, when a considerable part of the excess was largely the result of "minor" accidents. It is gratifying to note that the fatal accidents were 8.4 per cent. fewer. For many of the accidents the increasing use of machinery is responsible. The hours between 10 and 12 A.M. and 3 and 5 P.M. are those in which the largest number of accidents takes place. The large number of accidents for which shipbuilding is responsible is a matter recently recognized. In this industry more accidents happen to men under the age of 25 than to their elders. The inspector of the Midland Division draws attention to the fact that the number of accidents followed by blood poisoning is increasing. Slight wounds or abrasions which do not interfere with work at the time become infected, and are occasionally followed by a fatal result. Until lately there has been heard little of "needle puncturing" accidents. The subject is alluded to by one of the lady inspectors, who states that perforation of the hand by sewing-machine needles occurred in 40 instances last year. The greatest number of accidents occurred between the ages of 18 and 25, the group next in order being between 14 and 16. Very few of the accidents happened to workers over 25 years of age. As regards the trades in which the accidents occurred, blouse making headed the list, this together with skirt making being responsible for 50 per cent. of the total accidents. The largest number of such accidents apparently occurs at the prime of working life, when machines are run at the highest speed, and this is mostly in the blouse and skirt making trades. The substitution of electroplated for ordinary sewing-machine needles is said to contribute to safety, as they do not break so readily and if the finger is punctured less serious results follow.

Cigarette making as a home industry is said to be on the increase in London, a practice undesirable from all points of view, and yet one with which it is difficult to cope. The greatest offenders are workers of Russian and Polish origin. The total number of cases of lead poisoning for 1910 was 505, with 38 deaths, as against 553 cases, of which 30 ended fatally, in 1909, and 646, with 32 deaths, in 1908. China and earthenware trades were responsible for 77 cases, with 11 deaths; white-lead for 34 cases, and 1 death; and coachbuilding for 70 cases and 6 deaths.

Among house painters and plumbers, not included in the above notifications, there were 232 cases of plumbism and 35 deaths. At the Brussels Congress Drs. Agasse-Lafont and Heine of Paris read papers upon the condition of the blood in the presaturnine state, or what might be called latent saturnism, in which, while the system is impregnated by lead, as shown by the presence of the metal in the urine, the reaction on the part of the organism is so slight as almost to pass unobserved. They contend that in this presaturnine state, though the white corpuscles show nothing abnormal beyond a slight increase in the number of mononuclear cells in the blood, the red corpuscles, on the other hand, in addition to being slightly diminished in number, exhibit almost constantly basophile granules, and that some are also nucleated. Against this it is stated that neither Sir Thomas Oliver, King Alcock, nor K. W. Goadby has obtained any practical assistance from this as a sign of plumbism. The subject, however, is one which requires further investigation. The use of non-poisonous paints has proved so satisfactory in several of the large railway carriage works that the experiment is well worth extending. It yet remains to be seen how far lead sulphate can replace the carbonate and be free from risk. The use of lead paint for stenciling letters on goods wagons by means of aerographs is a source of danger. Arsenic and mercury as industrial poisons still claim victims, but fewer than formerly.

There were 51 cases of anthrax reported in 1910, compared with 56 for the previous year, the mortality rates being respectively 17.6 and 21.5. Considerable space is devoted to the subject of occupational dermatitis—a circumstance which suggests that skin affections in consequence of employment are on the increase. An interesting appendix on dermatitis caused in the manufacture of roll tobacco is from the pen of Dr. Collis. The eruptions were traced to the olive oil used in the process of spinning. The thin skin between the fingers and on the back of the hand and forearm becomes affected. The worker first feels the skin hot and irritable; it subsequently becomes dry and scaly; later it cracks, becomes red and inflamed, and pustules form. Apart from pain, the irritation of the skin causes a considerable amount of sleeplessness. The malady resembles eczema, and may spread by intercellular infection from the area originally affected. Removal from exposure to the olive oil is generally followed by recovery without further treatment, while resumption of the old work is followed by a relapse.—*British Medical Journal,* July 1, 1911.

Book Reviews.

THE PRACTICAL MEDICINE SERIES. Under the General Editorial Charge of GUSTAVUS P. HEAD, M.D., Professor of Laryngology and Rhinology, Chicago Post-Graduate Medical School, and CHARLES L. MIX, A.M., M.D., Professor of Physical Diagnosis in the Northwestern University Medical School. Volume IV: Gynecology. Edited by EMILIUS C. DUDLEY, A.M., M.D., Professor of Gynecology, Northwestern University Medical School; Gynecologist to St. Luke's and Wesley Hospital, Chicago, and C. VON BACHELLÉ, M.S., M.D., Assistant Professor of Obstetrics, Chicago Policlinic and College of Physicians and Surgeons; Gynecologist to the German Hospital, Chicago. Volume V: OBSTETRICS. Edited by JOSEPH B. DELEE, A.M., M.D., Professor of Obstetrics, Northwestern University Medical School. With the collaboration of HERBERT M. STOWE, M.D. Series 1911. Price $1.25. Chicago: The Year Book Publishers.

VOLUME IV of this series covers, in a brief way, the literature of gynecology of the past year. The value of the book has been enhanced by the pertinent comments which have been inserted by the editors.

Volume V contains a review of the literature on the investigations which have been carried on in the realm of obstetrics during the past year. Although very little has been accomplished we may in the near future reap great benefit from the work done. The editors have given a good synopsis of this work. The book should prove of value to the physician.

THEORY AND PRACTICE OF THYROID THERAPY. Being some experiences of the results of thyroid medication, with deductions concerning the influence of thyroid secretion in health and disease and certain effects of drugs and various circumstances upon thyroid secretion. A Book for General Practitioners. By HERBERT EWAN WALLER, M.R.C.S. (Eng.), L.R.C.P. (Lond.), Honorary Anesthetist Birmingham Dental Hospital, Medical Officer Balsall Heath Provident Dispensary. Price $2.00. New York: William Wood & Company, 1911.

THE author has performed a distinct service in writing this volume, which is unique in its discussion of a subject which concerns every practitioner. It is stated that an understanding of thyroid matters is essential to the practitioner in treating every case, and will materially improve his success in the treatment of fully one-fourth of his patients. The multiple rôle which the thyroid plays in the human economy is described in detail. Among the many phases of this rôle may be mentioned the need of the thyroid for calcium assimilation, deficiency of the thyroid causing rickety symptoms and dental caries; the thyroid treatment of obesity and of vomiting of pregnancy; the relation of calcium and thyroid to Graves' disease, goiter, and urticaria; the relation of iodine and meat to Graves' disease; the lymphatic glands and Graves' disease; thyroid and eczema; thyroid and arsenic; and the influence of salicylates and kindred drugs on thyroid activity. The value of thyroid medication in many morbid conditions, such as mental degeneracy, enuresis, and asthma, is fully discussed, as is also the mode of administering thyroid.

CARBONIC ACID SNOW: As a Therapeutic Agent in the Treatment of Diseases of the Skin. By R. CRANSTON LOW, M.B., F.R.C.P., Assistant Physician to the Skin Department, Royal Infirmary, Edinburgh. Price $1.50. New York: William Wood & Company, 1911.

THE application of carbon dioxide snow as a refrigerant in the treatment of many diseases of the skin is one of the most important advances within recent years in practical dermatology. The simplicity of technique renders this mode of treatment available to the general practitioner, who is now in a position to treat a large class of cases without the aid of the specialist. Diseases such as the various forms of nevus, and warts, papillomata, callosities, molluscum, powder stains, etc., are quickly removed by the use of this agent. The present volume supplies the information which will enable the practitioner to carry out the treatment successfully, describing the methods of application and the results obtained in the various diseases. In addition to the introductory chapter this volume consists of chapters on the following: the technique of collecting and applying CO_2 snow; the effect of carbonic acid snow on the skin; microscopical changes and experimental results, and therapeutic uses of carbonic acid snow. There is a series of sixteen excellent photographic plates illustrating the apparatus and technique, the microscopical effects of the refrigeration, and the appearance of cutaneous lesions after treatment with carbonic acid snow.

REPORTS FROM THE LABORATORY OF THE ROYAL COLLEGE OF PHYSICIANS, EDINBURGH. Edited by Sir JOHN BATTY TUKE, M.D., and JAMES RITCHIE, M.D. Vols. X and XI. Edinburgh: Oliver & Boyd, 1911.

THESE two volumes contain over sixty original papers issued from the laboratory of the Royal College of Physicians of Edinburgh in the years 1905 to 1910. The papers have for the most been published in various journals during these years. The subjects are mostly anatomical and pathological. But a few titles can be named in this review: The Vermiform Appendix of Man and the Structural Changes Therein Coincident with Age, by J. A. Berry and L. A. H. Lack; the Bacteriology of Aural and Nasal Discharges in Scarlet Fever and Other Diseases, by C. J. Lewis; the Duration of Vitality of *B. coli communis* in Various Waters and in Sewage, by J. G. McNaught; An Experimental Investigation of Infective Sarcoma of the Dog, by Henry Wade; Experimental and Clinical Observations on the Urine and Blood in Nephritis, by J. L. Green, etc., etc.

THE high reputation of this laboratory is well supported by the character of the papers gathered in these volumes. For the most part they represent real additions to our anatomical and pathological knowledge. The idea of issuing them in one volume is a good one, for in a great many of them the same central idea of research is dominant, as might be expected from workers in one laboratory. The volumes, too, present a much more pleasing addition to one's library than would numerous separate reprints of the same papers.

LEITFADEN DER AKUSTIK FÜR OHRENÄRZTE. Von Dr. M. TH. EDELMAN, Prof. h. c. der Kgl. tech. Hochschule München. Mit 80 Abbildungen und einem Porträt. Berlin: Verlag von S. Karger, 1911.

THIS volume of 118 pages discusses the elements of acoustics and describes the selection, use, and adjustment of the various instruments used by the aurist, some of which are of recent introduction. The book is practically a supplement to Bezold's well-known textbook on diseases of the ear, taking up purely the physical and technical aspects of this subject.

ÜBER SCHARLACH (Der Scharlacherkrankung zweiter Teil). Von Dr. DIONYS POSPISCHILL, k. k. Primarärzt, und Dr. FRITZ WEISS, gew. Assistant der Abteilung. Mit 14 Kurven. Berlin: Verlag von S. Karger, 1911.

IN this monograph the author has taken as his theme the phenomenon which among all the acute infectious diseases seems to be peculiar to scarlet fever, namely, the recurrence of subjective and objective symptoms after an interval of freedom from symptoms—a sort of second invasion of the disease. The latter would apply to the so-called complications occurring in the second and third weeks, such as nephritis, otitis, adenitis, and fever. This subject is discussed in a thorough and interesting manner.

HEREDITY IN THE LIGHT OF RECENT RESEARCH. By L. DONCASTER, M.A., Fellow of Kings College. Price 40 cents. Cambridge: University Press, 1911.

THIS little volume of 143 pages forms one of the Cambridge Manuals of Science and Literature. It is a scholarly exposition of the various aspects of heredity; its relation to variation, its statistical study, and its causes. Mendelian heredity is clearly described. The chapter on heredity in man, including a discussion of the rôle of heredity in diseases, is one that will particularly interest the physician.

LEHRBUCH DER SPEZIFISCHEN DIAGNOSTIK UND THERAPIE DER TUBERKULOSE. Für Aerzte und Studierende. Von Dr. BANDELIER. Chefarzt des Sanatoriums Schwarzwaldheim in Schömberg bis Mildbad, and Dr. ROEPKE, Chefarzt der Eisenbahnheilstätte Stadtwald in Melsurgen bis Cassel. Sechste erweiterte und verbesserte Auflage, mit einem Vorwort von Wirkl. Geh. Rat Prof. D. R. KOCH, Exzellenz. Mit 19 Temperaturkurven auf 5 lithographischen Tafeln, 1 farb. lith. Tafel und 5 Textabbildungen. Price 6.60 Marks paper, 7.80 Marks bound. Würzburg: Curt Kabitzsch, 1911.

IN the sixth edition of this excellent work, which follows the fifth with the briefest interval, that having been reviewed in these columns only about six months ago, no very great change has been made. A short chapter on the specific treatment of aural tuberculosis has been introduced and in the other chapters on treatment everything of importance that has appeared during the past year is noted. The preface to the third edition, written by the lamented Koch a year before his death, is reproduced in this edition, which also is dedicated "To the Great Master, Robert Koch."

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON MEDICINE.

Stated Meeting, Held October 17, 1911.

DR. H. S. PATTERSON IN THE CHAIR.

A Case of Thoracic Tumor and Aneurysm of the Descending Thoracic Aorta, Treated with Salvarsan.—Dr. GEORGE REESE SATTERLEE presented a patient, fifty years old, a chef by occupation. He had measles when a child and yellow fever in 1874. Twenty-five years ago he had an attack of jaundice with pain; this sickness lasted nine months and it took nearly two years to clear up the jaundice. He had an attack of gonorrhea thirty years ago with a chancre, said to be a soft one. He had local treatment only. He had no eruption and did not know that he had syphilis. His present illness began four years ago with "indigestion" for which he was treated in New York Hospital O. D. P. He had pain in the back and dyspnea. He was then treated in the Board of Health tuberculosis clinic. A diagnosis of tuberculosis was made and he was sent to Otisville, where he became worse; the pain was very severe and he could not work. He then went to Denver and Colorado Springs, where he became much worse with severe pain in the back and dyspnea. He was told he had pulmonary tuberculosis. Fourteen physicians in New York City had treated him. On admission to the University and Bellevue Hospital Medical College Dispensary he complained of severe pain in the left side of the chest, epigastrium, and in the left shoulder. The pain was continuous and prevented him from lying on his back. He was hoarse and he had dyspnea on exertion. There was a paralysis of the left vocal cord, but no other syphilitic manifestations. The superficial veins on the left side of the chest and over the left sholder and arm were enlarged and tortuous. The heart showed a moderate hypertrophy and an area of dulness in the first left interspace. There was no pulsation, murmur, or tracheal tug evident. The pulsation in the left radial artery was almost obliterated. The diagnosis of thoracic tumor, possibly an aneurysm, was made and a radiograph showed a rounded mass at this spot and an apparently dilated descending thoracic aorta. The mass seemed to be in the region of the aorta and it seemed as if it was separate from the aorta. There were no positive evidences of tuberculosis. There was a positive Wassermann reaction. Salicylate of mercury was given intramuscularly and then about 0.4 gram of salvarsan was injected into the gluteal muscles. Two and a half days after salvarsan was administered the improvement was wonderful. The left radial pulsation returned in full, a sensation to this effect being noticed by the patient. His general condition began to improve immediately and the pain was relieved. The voice began slowly to improve also. Instead of the paralysis there was just a little weakness. This was followed up by doses of salicylate of mercury, grain 1, into the buttocks twice a week; iodide of potassium up to grains xx three times a day was given. A second dose of salvarsan, 0.3 gram, was given and this was followed by iodide of potassium, 40 grains a day, and salicylate of mercury twice a week. Gradual improvement took place. The Wassermann reaction was negative. The second series of radiographs failed to show any apparent diminution in the size of the tumor. The examination of the larynx showed slight weakness of the left vocal cord. He still had some pain in the back and some dyspnea on exertion. The fluoroscope showed pulsation in the tumor mass in front and behind which pointed to the existence of an aneurysm. The polygraph tracings showed a normal heart and circulation.

A Case of Syphilitic Aortitis Treated with Salvarsan.—Dr. FREDERICK FRANCIS KOSAK presented a patient, forty years old, a cooper by occupation. He received his initial lesion thirteen years ago for which he was treated locally and internally for six weeks, during which time the chancre healed. With this exception the patient stated that he was in comparatively good health until a year previous to the time he first came under observation. At this time he was suffering from dyspnea, feeling of oppression in the upper chest, flashes of light before the eyes, and dimness of vision. These symptoms were almost constant up to the present time, when they became more exaggerated, so much so that he could not sleep lying down. It was for these symptoms that he applied for treatment. The physical examination showed a patient fairly well developed; there was no enlargement of the thyroids; the heart was enlarged, the apex extended four inches from the median line and was at the fifth interspace, and the right side was slightly beyond the right margin of the sternum; there was a double aortic murmur. The aorta showed marked dilatation. The *x*-ray verified these findings. The liver and spleen were not palpable; there was no change in either radial or popliteal pulses. There was a moderate arteriosclerosis; the blood-pressure was 100 mm. The Wassermann reaction was markedly positive. During September salvarsan, 0.3 gram, was administered by the intravenous method. One hour after the blood-pressure rose to 105 mm. With the exception of a slight rise of temperature, which soon became normal, the patient was in such good condition that he decided to go home, where he returned to his occupation, doing light work. About the fifth day the burning sensation behind the sternum returned, and on the tenth day became so marked that he returned to the hospital suffering from extreme dyspnea, palpitation, pain over the precordium, and with a severe cough. The physical examination at this time showed the apex behind the sixth rib, four inches from the median line; there was a loud systolic murmur transmitted to the back. There were a presystolic murmur at the aortic orifice and a number of moist râles in the interscapular region and base of the lungs. Under the application of ice, rest, and a fluid diet he gradually improved and was discharged on October 14, two weeks after his admission. The blood-pressure during this period varied between 90 and 100 mm. The examination of the urine was always negative. The blood examination on admission showed 3,000,000 red cells with 85 per cent. hemoglobin. When the patient was discharged there was a slight increase in the latter to 90 per cent. The leucocytes were normal and remained unchanged. The temperature, pulse, and respirations were practically normal during his stay in the hospital. The patient now could sleep lying down, felt much better, and except for an occasional pressure over the precordium had never felt as good in the past year. Much had been written on the contraindications of salvarsan in complicated cardial and vascular diseases. The presence of endomyocarditis, aortitis, and arteriosclerosis raised the question, Were they justified in administering salvarsan in this case? In reviewing the literature they found that very few cases had been reported in which salvarsan had been tried in these cases, and in all such reported cases the results had been very encouraging. The general physical condition of the patient and the belief that his aortitis and endocarditis were due purely to his specific condition led them to administer a small dose of salvarsan with the idea of repeating the same if the results were favorable. To attribute the acute dilatation developing ten days after the injection to salvarsan brought out a question yet to be decided. Had the patient been kept longer in bed with proper diet this dilatation probably would not have occurred. Its subsidence in a few days strengthened this belief.

Dr. G. R. Satterlee said that after the salvarsan was given there appeared some burning along the aorta. The man's condition now was not good. He had some dilatation of the heart and he was not cured.

Diagnosis of Gastrointestinal Conditions by Means of the Röntgen Rays.—Dr. George Reese Satterlee and Dr. Leon Theodore Le Wald presented this communication in part. The paper was read before the Section on Medicine at the Los Angeles meeting of the American Medical Association, and was abstracted in the Medical Record of July 8, 1911, page 98. To illustrate the paper the following cases were presented.

Case I.—This patient was a woman, twenty-seven years old, and ever since childhood had been constipated and had to take cathartics and laxatives. For the past two years she had been getting worse and vomited one-quarter to one-half hour after meals. She had pain which was most marked in the epigastrium. In January, 1911, she developed hemorrhoids, which were removed. Since the operation the symptoms had continued; there were cramp-like pains in the abdomen after eating, flatulence, very severe constipation, vertigo, flashes, vomiting, and loss of weight. Her diet was reduced to a very low amount. The medical treatment consisted in the use of water, sodium phosphate, agar agar, bran biscuits, olive oil by mouth and rectum, but it was of no avail. Her weight from March to August dropped from 127 to 109½ pounds. The stools were very dry, hard, and contained undigested food. In May, 1911, the bismuth-Röntgen ray test was made. This showed a long, ptosed, and sluggish colon. The stomach was normal. It required six days for the entire intestinal tract to empty. On August 6 the patient had a typical attack of appendicitis. On August 11 a laparotomy was performed and the colon was found as diagnosed by the bismuth-Röentgen ray. An appendectomy was done and the transverse colon was sutured across at the umbilicus to the abdominal wall. Since then the patient had gained in weight and returned to her work, but she was still suffering from constipation.

Case II.—This patient was a woman, thirty-one years old, housewife. She had had measles, pneumonia three times, and diphtheria. Her personal habits were good. Five years ago she weighed 160 pounds; one year ago she weighed 135 pounds; she now weighed 102 pounds, a loss of 58 pounds in five years and 33 pounds in one year. She had had attacks of vomiting *every two weeks for one year*. Her illness began with loss of appetite, vertigo, flatulence, and then she would vomit everything she had eaten. In between the attacks she felt fairly well, but there continued this gradual emaciation. She was admitted to the Washington Heights Hospital, July 8, after a vomiting attack. She was extremely nervous, complained of insomnia, and was very much emaciated. Percussion of the stomach showed that it was very large and low. The use of the test meal and lavage was impossible on account of her nervous condition. The urine was normal and the blood showed a moderate anemia. On July 22 she had a vomiting attack lasting two days. The bismuth-Röntgen ray test revealed a ptosed stomach with the greater curvature six inches below the umbilicus. The emptying of the stomach took five hours. Aside from a moderately long and ptosed colon with a four-day motility (complete) it was normal. The patient was placed in the Goldthwaite position in bed, and this was followed by a very severe attack of vomiting lasting two days. This made the patient feel very feeble, necessitating rectal feeding. She vomited blood and became very hysterical. Operation was then decided upon. On August 12, at St. Luke's Hospital, Dr. John Douglas operated. The stomach was found to be very low, the lesser curvature being below the umbilicus; the pancreas appeared above it. The gastrohepatic omentum was very thin and stretched. The duodenum was in the normal position. The colon was low in the pelvis. The large veins of the stomach were much congested. The gastrohepatic omentum was too thin to suture; therefore the ventral surface of the stomach was sutured to the peritoneum of the abdominal wall by two chronic gut sutures, the gastrocoloic omentum being also sutured just below the stomach to the peritoneum. The right kidney was not movable. The patient made a good recovery. She vomited some blood on the day following the operation. She had an attack of hysteria in the bath room. On September 6 an abdominal binder was applied, her diet was carefully regulated, she was made to rest, malt extract was ordered, etc. On September 10 she was unable to sleep well and had pain in the right side of her abdomen. Turpentine stupes were ordered and an abdominal webbed belt with a colon pad was applied. On September 13 her condition was much improved. On October 4 she weighed 104½ pounds and had diarrhea after eating.

Dr. Leon Theodore Le Wald gave a lantern slide demonstration showing the results as to the position, size, shape, and motility of the colon which had been very satisfactory. The organ could be readily identified by its size, position, and sacculations. They had classified the cases into (1) normal colons, (2) abnormally long and looped colons, (3) ptosed colons, with or without abnormal length and loops, and (4) abnormally short colons. As to the shape of the colons, the following terms had suggested themselves:—(a) straight, transverse colons, the strictly normal; (b) the U-shaped colon, caused by one loop dipping down toward the pelvis; (c) the V-shaped colon, which was similar; (d) the double U-shaped colon, with one loop from the hepatic and another from the splenic portions of the transverse colon; (e) the W-shaped colon, similar to the last; (f) the diamond-shaped colon, with the transverse portion running abruptly upward from the hepatic to the splenic flexure; and (g) the dragon-shaped colon. Their control radiographs showed the constancy in the shape and position of these colons and in their estimation proved them to be peculiar to the individual.

Dr. Herman Fred Lange Ziegel reported the case of a man 55 years old who came under observation 10 months ago with the history that for a number of years there had been epileptiform convulsions occurring two to four times every day and that for several months there had been dyspnea, cough, and severe pain in the right infraclavicular region. On the day before admission to Beth Israel Hospital there was a large hemoptysis. Examination showed signs of marked arteriosclerosis, with accompanying high blood-pressure, hypertrophied heart, etc. The right radial pulse was smaller than the left. There were dullness, bulging, and tenderness below the right clavicle, but no pulsation. The exact cause of the convulsive seizures was not determined, though cortical gumma and nerve pressure from aortic aneurysm were considered. The Wassermann reaction was positive. Salvarsan, 0.5 gm., was given intramuscularly in alkaline solution. Severe pain followed the injection, four or five days after which the Wassermann reaction was negative. The symptoms improved greatly—the pain in the right upper chest disappeared, and the convulsions diminished considerably in both frequency and severity. The serum test, performed from time to time after the treatment, remained negative for about six weeks, when it again became strongly positive. At this time Dr. Robinsohn, Dr. Ziegel's successor in the hospital service, wanted to readminister salvarsan, but the patient refused. When casually met seven months after the treatment, the patient complained of the same infraclavicular pain and the convulsions had recurred, less frequent and severe, however, than formerly. The result in this case confirmed the view

that salvarsan was not usually dependable for lasting effects and that in such a case it should perhaps be readministered one or more times, but that by all means it should be followed up by prolonged mercurial treatment.

Dr. Anthony Bassler said that good quality of gastro-intestinal work was to-day not possible without the use of the *x*-ray. He felt that one should always be conservative in making positive diagnostic conclusions from plates and fluoroscopic observations, and that plates must show the same findings in a series before we were warranted in making diagnoses in the majority of cases. He drew attention to the fact that, whereas it was a most valuable method of examination, it occasionally failed in suggesting a condition that should be seen by it, and in some simple disorders plates were obtained that strongly suggested extreme conditions. He said that it was necessary for diagnosis that the anatomy of the organ be changed in a definite and permanent way, and that it was in the field of work of the transit of bismuth through the alimentary tract as presented in the paper read that the worst mistakes were possible. He then showed plates that he had made of cases under his observation, preceding the diseased conditions of the esophagus, stomach, and colon, with normal plates showing important points in the physiology of motility in these structures. Among the latter of these he demonstrated that during rest, the esophagus was depressed antero-posteriorly by the base of the heart, and that the lower end of the gullet was funnel-shaped; the separation of food in a full stomach from the lesser curvature when fluid was swallowed forming the "water street" in which the fluid ran off into the duodenum, leaving the food in the stomach, the phenomenon of the pyloric reflex in the production of the pyloric shortening and rounding, the incisura angularis, the closing of the sphincter muscle, and the regurgitation of fluids from the beginning of the third part of the duodenum back to the height of the horse-shoe course before it flattened out for its onward course; normal stomach motility; and the positions and size of the normal esophagus, stomach, and colon. He then showed plates of the following conditions: carcinoma of the cardia, neurotic hypermotility, cirrhotic gastritis, acute and chronic gastric ulcers, different extents of gastric carcinoma, various types and combinations of splanchnoptosia, angulations and permanent obstructions of the colon, chronic appendicitis, and redundant and looped sigmoids. Some of the plates he drew particular attention to formed a set which showed the benefits that had been brought about from one month's treatment with thymus extract in a case of gastric carcinoma, the fact that redundancies and angulations of the colon and sigmoid could only be diagnosed by this means, which made him wonder that those engaged in rectal work did not take advantage of this means of examination more frequently than they did, and the demonstrable benefits that came from the rest, dietetic, and mechanical method of treatment in the splanchnoptosia cases.

Accidents and Deaths from Exploratory Puncture of the Pleura.—Dr. Hughes Dayton read this paper. He said that among the accidents which had been recorded as resulting from simple exploratory puncture of the pleura a fatal outcome had been noted as a result of pneumothorax, puncture of a hydatid cyst, perforation of the diaphragm, stomach, and liver, hemorrhage from an intercostal vessel or the lung, and pleural reflexes. The records of about 20,000 consecutive admissions to the medical wards of the New York Hospital included one case of breaking of the needle in the chest wall, three of subcutaneous emphysema, one of puncture of an abscess of the lung, followed by septic symptoms, four of hemoptysis, one of puncture of an aortic aneurysm, one of syncope, and one of death after sudden onset of grave cerebral symptoms. From the histories of these cases and from a review of the literature, including 21 cases of pleural reflexes, and excluding from consideration all accidents resulting from aspiration, it was seen that: 1. Breaking of the needle involved the danger of the presence of a foreign body. Its prevention demanded only ordinary care and skill and restriction of movement of the patient. 2. Localized pleurisy could not be prevented, but the pain might be relieved by strapping or local applications of heat. 3. Subcutaneous emphysema was rarely productive of more than slight discomfort and perhaps an alarming appearance, unless accompanied by cellulitis. It could not be prevented, but rarely required treatment. As a complication of pneumothorax it might even act as a safety valve, hastening resorption of air. 4. Pneumothorax could not always be avoided. Its importance depended upon the physical condition of the site of puncture as regarded the possibility of spontaneous closure of the puncture, and upon the condition of the patient. 5. Infection of the pleura from without might be prevented by aseptic technique, and its occurrence was probably comparatively infrequent. That from foci of infection within the body cavity could not be avoided. If empyema resulted the treatment was surgical. 6. Puncture of a hydatid cyst of the lung was a rare but not a serious accident. Radiographic examination might show a shadow whose rounded outline would suggest the presence of a cyst rather than a pleural effusion and favor exploratory incision rather than puncture. 7. Puncture of the diaphragm with peritoneal infection from an intrathoracic focus might sometimes be avoided by radiographic determination of the level of the diaphragm. 8. Prevention of perforation of the heart, stomach, liver, or spleen, with possible infection or hemorrhage, called for reasonable care as to the site and depth of puncture. Its occurrence, if results were serious, demanded an early diagnosis and immediate surgical treatment. 9. Perforation of an aneurysm of the descending aorta submerged by fluid, as in the case recorded, and giving no definite signs, could be avoided only by puncturing as far as possible from the median line. In the reported case this would have been beyond the posterior axillary line. 10. Hemorrhage from an abnormally placed intercostal vessel could not be foreseen. Sudden increases of pleural effusion with symptoms of internal hemorrhage or profuse bleeding from the site of puncture required incision and ligation. Hemorrhage from the lung was shown by the twenty-one cases to occur most often in cases of consolidation; 33 1/3 per cent. of these resulted in death. Unnecessary movement of the needle within the chest should be avoided. 11. Albuminous expectoration, which usually occurred only after withdrawal of a pleural effusion, had resulted from puncture, being probably due to reflex vasomotor changes. 12. Pleural reflexes, cardiac or respiratory failure, convulsions, coma, paralysis, etc., resulted from stimulation of branches of the vagus nerve, probably in the visceral pleura, but possibly in the lung. These accidents occurred most often (at least 76 per cent.) in cases with consolidation of the lung, usually due to a chronic inflammatory process. The precautions in performing exploratory puncture of the pleura which an analysis of 23 cases of accidents due to pleural reflexes suggested were: (1) Avoid moving a patient with pneumonia or pleurisy with effusion, especially avoid moving him from the recumbent to the sitting posture. (2) Avoid turning him onto the sound side. (3) Avoid excitement before the operation. (4) Use as small a needle as would suffice and avoid all unnecessary shock, as this was badly borne by cases of pneumonia. A small trocar inserted through a skin incision might be safer than a needle, as it was less likely to lacerate the visceral pleura and lung. It should be introduced only far enough to obtain fluid. (5) Never use the exploring needle as a labor-saving device if a careful study of physical signs

would suffice. (6) Cases with a probable consolidation should be punctured only when a definite indication for diagnosis or treatment existed, *e.g.* the probable presence of pus as shown by the temperature curve and increasing polymorphonuclear leucocytosis, or extreme and increasing signs of fluid indicated by displacement of the apex beat or by respiratory embarrassment. In a case beginning as a definite lobar pneumonia it was often more conservative to wait until after the crisis before exploring unless the symptoms suggested the necessity for early operation if pus should be found. In such a case rapid resolution might remove the signs which simulated fluid. If the signs were such, however, as to prevent a clear diagnosis of the intrathoracic lesion, and empyema was suspected, exploration should be made without delay, especially in children. More lives were probably lost by delayed diagnosis of empyema than by all the accidents due to exploratory puncture of the pleura.

Dr. Morris Manges said that if there was any place where a warning was needed it was in the city of New York; anyone who had done hospital work knew how common were accidents associated with explorations of the chest. He always felt that the use of the exploring needle was much abused, especially in hospital work. Fortunately, this did not apply so much to work in private practice. When Dr. Manges was a junior in the hospital a case of sudden death occurred from a simple exploratory puncture; Dr. Biggs was the curator at the time, and he said that this was an unnecessary death, because it was caused by an exploratory aspiration. The patient had emphysematous lungs, and there had occurred a perforation of an air vesicle which resulted in the death of the patient. This accident occurred in 1888. He had seen many accidents since, most of which were of minor consequence. Only one week ago he saw a very difficult case of interlobar empyema, the diagnosis of which was confirmed by the *x*-ray; in the attempt to find the pus a pneumothorax occurred. Not only was the patient not benefited by this exploration, but she was made worse, as it was now an inoperable case, since it was now a case of interlobar empyema in a collapsed lung. There was also a paralysis resulting from an embolus after the exploratory puncture. Dr. Manges had observed such a case; it was not after a thoracentesis, but after an exploration of the pericardial cavity. Some three years ago he saw a patient with a tuberculous pericarditis; three days after aspiration of the pericardium a cerebral embolism occurred, the results of which were demonstrated four months later at autopsy. This patient died of an acute miliary tuberculosis, and not from the embolism or from the pericarditis. Dr. Dayton in his paper had referred to the visceral reflexes. The embolism in the case of Dr. Manges referred to occurred three days after exploration and not immediately or within twelve hours after, as in the cases usually reported. The embolism was due to a loosening of a thrombus in the pulmonary vessels; on account of the impairment in the circulation the formation of a thrombus was favored, and where the dynamic conditions were so changed it was very easy for a clot to become loosened and an embolus to form. There was one thing in the paper that they should carry home with them. What Dr. Delafield had said about the treatment of pleural effusions was not correct in all cases; in the city of New York they seemed to think this was the right treatment. Dr. Delafield's dictum was, "If pleural effusion anywhere, empty it." That was not accepted everywhere. All cases of pleural effusion, whether the result of tuberculosis or not, should not be emptied indiscriminately. In many cases of tuberculous effusion the fluid was of distinct benefit in the early stages, provided the amount was not too large. The lymphocytosis and the antibodies contained in the effusion were a part of nature's defense against the tuberculous process in the lung.

MEDICAL SOCIETY OF THE STATE OF PENNSYLVANIA.

Sixty-first Annual Meeting, Held at Harrisburg, September 25-28, 1911.

(*Continued from page 947.*)

SECTION ON SURGERY.

Tuesday, September 26—First Day.

Traumatic Surgery of the Hand and Foot.—Dr. James Jefferson of Johnstown read this paper. He said that during the past six years he had been associated with a large industrial hospital where an average of 150 traumatic cases were cared for daily. The most important feature in traumatic surgery of the hand was in the care of severed tendons. In suturing tendons the approximation had much to do with the efficiency in such position as to avoid tension on the sutures. The best method of treating metacarpal fractures was by a long palmar splint with adhesive strips at the wrist for counterextension and two strips of adhesive applied to the finger after the manner of Buck's extension. The severely crushed finger should be thoroughly cleansed, the soft structures replaced, and a hot bath of 1/4,000 corrosive sublimate applied. There was a great temptation to amputate, but it paid to take time and patience to avoid this. For sprains of the ankle his custom was to apply a plaster cast with the foot at right angles to the leg and follow this later on by strapping after the method of Gibney.

Dr. J. Stacey John of Bloomsburg said that *x*-ray examination in all castes of injuries of the hand and foot was of the gravest importance. In all injuries of the hand and foot an examination should be made to determine if any of the tendons had been severed. If so they should be sutured with catgut.

Dr. A. R. Allen of Carlisle thought the first thing that deserved consideration in these injuries was conservatism. When there was infection there should be free incision and immobilization. In dressing cases of fracture he used a small splint made up of adhesive plaster with a small strip of pasteboard enclosed within it and it answered very well. The application of tincture of iodine to the wound and surrounding tissues produced practically perfect sterilization.

Injuries of the Shoulder and Their Relation to Some Conditions of the Upper Extremity of Obscure Origin.—Dr. T. Turner Thomas of Philadelphia presented this paper. He called attention to the fact that these injuries were more frequently associated with dislocation of the shoulder than with any other definitely established traumatic condition. In those cases in which there was no history of dislocation either it was spontaneously reduced or the tear of the capsule was not extensive enough to permit the humeral head to escape from the glenoid cavity. The diagnosis must depend chiefly upon the statements of the patient as to the nature of the accident and the symptoms. In the early stages there was found severe pain on abduction and external rotation. The condition persisted throughout life often, but even in the oldest cases it could be overcome. Under a general anesthetic the contracted capsule was torn, the arm forced into full abduction and maintained in that position for several weeks. The arm was then allowed to come down to the side and treatment continued by suitable massage. Dr. Thomas had done this with excellent results in every case. More troublesome than the pain was the more or less severe palsy of the limb, due to injuries to the brachial plexus or its roots. There were two types of these cases, one in which the humeral head was maintained at its normal level and the other in which the muscles and ligaments were relaxed and the humeral head fell considerably below the head of the acromion. In the latter variety there was no tendency toward recovery. He believed these flaccid

shoulder joints were not due to injuries of the brachial plexus, but to anterior dislocations of the shoulder. The operation which he did in those cases was to shorten the upper and posterior portion of the capsule and the overlying external rotator muscles.

Dr. William L. Estes of South Bethlehem said that in men who were especially liable to or who had had gout or rheumatism and especially lithic acid involvement of their blood he had noted that they were the ones especially who had this subsequent paresis following injuries to the shoulder.

Dr. S. J. Waterworth of Clearfield agreed with the author of this paper that a large percentage of these cases were caused by forceful abduction, and his personal experience with two operative and about a dozen other cases led him to believe that the paralysis was due to inflammatory products pressing upon nerve tissues. He was thoroughly in accord with the author's method of treatment.

Dr. Edward Martin of Philadelphia said that the argument that subacromial bursitis could not produce the symptoms of a paralytic, painful, and useless shoulder was not convincing to one who had seen these symptoms disappear upon removal of the inflamed bursa. There were indubitably a certain number of cases of crippled shoulder due entirely to traumatic bursitis. Thomas in his splendid detailed study had shown how to cure many cases not at all amenable to the bursitis operation.

Dr. Americus R. Allen of Carlisle said he could not understand why these cases should recover so quickly when there was an involvement of the nerve itself. Therefore he felt there was a condition existing around the shoulder-joint that was due to the inflammation of this bursa, but that not every pain or tender spot around the joint was bursitis.

Some Practical Considerations in the Treatment of Backward Displacements of the Uterus.—Dr. Xavier O. Werder of Pittsburgh said that a simple uncomplicated uterine displacement rarely justified operative treatment, because this malposition was usually a harmless condition. When symptoms accompanied a uterine displacement careful search should be made for some pelvic complications which are usually responsible for the disturbances, and in the absence of such affections careful examination into the general condition of the patient and especially for some manifestation of this trouble should be made. When in doubt, as of necessity one would often be in this class of cases, a temporary correction of the displacement by means of a well-fitting pessary would often determine whether the cause of the ailment could justly be attributed to the uterus or to some derangement of the general health of the patient. Thus the pessary would often prove a valuable diagnostic as well as therapeutic agent.

Dr. Lowell M. Gates of Scranton thought that, while all cases of retrodisplacement of the uterus did not need immediate operation, sooner or later they would. He thought that in time the retrodisplacement would produce symptoms of interference with the proper circulation of the blood in neighboring organs. We must always consider the type of the patient. A phlegmatic woman of the ordinary walk of life would go around for years with a retrodisplacement of the uterus without paying any attention to it, while the neurotic was made uncomfortable. It was not every person who would allow surgery and therefore a pessary came in handy and in some cases cured the disease.

Secondary Repair of the Perineum by the Emmet Method.—Dr. Henry D. Beyea of Philadelphia presented this paper. He said there was much evidence of a widespread tendency to discredit the value of the Emmet operation, the secondary repair of the perineum. It was the purpose of this paper to enter a plea for the continued practice and better understanding of this operation. There was no operation in surgery that was more difficult of understanding, that required more study and surgical skill in its performance than this one. To properly teach this operation practical demonstration by the surgeon himself was necessary. It was essential to practise every detail of the operation as taught by Emmet even to the needle and suture material. As properly practised it stood, as it had for the last twenty-five years, the only anatomically and surgically correct and the most efficient method of restoration of the injured pelvic floor and the relaxed vaginal outlet.

Dr. Theodore B. Appel of Lancaster said that personally in his own work on the perineum the results of the Emmet operation had not been very satisfactory. His object in these cases was to get after the weakest point. Whether one could do that by an operation carried on according to the lines that Dr. Beyea spoke of he questioned.

Dr. J. W. Luther of Palmerton agreed fully with Dr. Beyea in believing that the Emmet operation could not be taught properly without practical demonstration. He thought, however, it was a mistake to try to apply one operation to all cases. If a distinct sulcus laceration could be demonstrated, he thought the Emmet operation, which attacked the point of laceration, was the operation of choice. There were a great many cases of relaxation of the pelvic floor occurring in women either with or without laceration. In those cases in which a distinct sulcus tear could be demonstrated he thought the Hegar operation superior to the Emmet.

Dr. W. Wayne Babcock of Philadelphia said that there was no doubt that Emmet's operation had served a very useful purpose in the development of gynecological surgery. The Emmet operation was a gynecological procedure and not a surgical procedure. One had in the relaxed perineum a condition very similar to that occurring in a hernia. By bringing its walls in apposition one could repair a perineum that was relaxed in just the same way that a hernia was repaired. There was no reason why one should not expose the various layers of tissue and bring them together.

Dr. J. M. Baldy of Philadelphia said that his own impression had been that an operation was always surgical providing the man knew how to do surgery. The trouble with those who criticized the Emmet operation was that they did not know how to do it. They showed this by their criticism. The fault had been with the gentlemen who had tried to modify the Emmet operation. They had not done the Emmet operation. There was no such thing as a relaxed perineum without a laceration.

Dr. R. C. Norris of Philadelphia said that the Hegar operation was suited only to women who would not again bear children, while the Emmet operation was adapted to child-bearing women. The whole difficulty lay in the lack of knowledge of the anatomy. He advised all to go back to anatomy and study the anatomical basis of these operations and then one would learn the true principle involved.

Intussusception in Children.—Dr. A. Ralston Matheny of Pittsburgh read this paper. He said that intussusception in children was usually of the acute type and therefore usually surgical. Early diagnosis and surgical interference were essential to a low mortality in acute cases. The operation should be simplified as much as possible and this could be done only while the invagination was reducible. The mesentery in children was long. Therefore pitching or swinging them violently should be advised against. Digital examination of the rectum was most important in children suffering from acute abdominal pain.

Dr. G. W. Wagoner of Johnstown said it seemed scarcely possible that any other treatment than operation was ever justifiable in these cases. There were many cases in

which the parents refused operation. Lavage and injection into the bowel might be of value during the first 48 hours. There was no question that opium in certain cases relieved the immediate condition. But he was strongly of the opinion that the only scientific treatment was surgical.

Dr. Americus R. Allen of Carlisle said he had seen a few of these cases. The only thing to do was to make an early diagnosis and to operate immediately. Measures which tended to delay should be condemned. One should recommend operation and if it was refused throw the responsibility on the parents.

The Etiology and Surgical Pathology of Impaired and Obstructed Gastric Drainage.—Dr. Levi J. Hammond of Philadelphia said that up to December, 1910, he had treated surgically 70 cases of prepyloric or duodenal, disease, including mechanical obstruction by angulation from adhesion to neighboring organs or viscera, malignant tumors, gastric ulcer, perforating duodenal ulcer, chronic duodenal ulcers, and benign stenosis. In the group of malignant tumors 21 belonged to the inoperable class in which treatment was hopeless so far as a cure was concerned, though he did not recall any instance in surgery where prompt temporary relief could be given, this being accomplished by posterior gastroenterostomy, which should alone be the procedure employed. Medical treatment should not be employed before operation in these malignant cases until it had ceased to be of value, for, if thus delayed, surgery could not contribute its full measure of relief.

Wednesday, September 27—Second Day.

Chairman's Address.—Dr. J. M. Wainwright of Scranton delivered this address. He said that surgeons could very well devote more time to the study of how to avoid operations which must end fatally, how to make all operations safer, and how to diminish postoperative discomfort. In the ideal stage of surgery there would be no postoperative deaths, which now resulted either because the operation had been bungled or else because death was inevitable in spite of operation. In the latter case we had deluded ourselves into thinking that the operation would give the patient the last chance, whereas, in fact, all the operation did was to hasten the end. We needed to make marked improvements in reference to the question of the safety of operating. We must learn among other things how to avoid influencing the blood-pressure and also how to use the anesthetic. Something must be done to make convalescence more pleasant. Patients did not get vitally interested in surgical feats performed while under the anesthetic, but they were vitally interested in the discomfort they suffered after the operation.

Estimation of Vital Resistance of Patient with Reference to Possibility of Recovery.—Dr. J. C. Bloodgood of Baltimore, Md., presented this address, saying that for estimating the resistance of the individual we had very few scientific methods and instruments of precision as compared to those which the engineer possessed. In estimating the factors of vital resistance there were two large problems, one of diagnosis and one of treatment. The patient must be under observation from beginning to end and we must be changing our methods in order to meet the indications. As we had progressed in surgery and eliminated the grosser problems we came to-day to problems of the most minute detail. Now this relief with recovery depended upon the estimation of the vital resistance of the patient before, during, and after operation. When we came to estimate the actual factors in the resistance of the individual science was small as compared to the art. We had to consider, first, the individual; second, the operation, and, third, the disease. Whenever we could estimate that the relief from the burden of the disease was greater than the burden we were going to place upon them by an operation, the chances for a cure were very great. In regard to anesthesia, his personal experience in the last year had demonstrated that operations could be done with nitrous oxide on handicapped individuals, operations of a greater magnitude with the risk tremendously less than the same operation on the same individual under ether. During the operation the surgeon and the anesthetist worked together, estimating the factors of shock, following pulse and respiration, and the surgeon must learn when to stop. There were many operations which need not be finished and Dr. Bloodgood thought careful observation would teach us when to stop in some of these operations of greater magnitude on handicapped individuals and we would perform the operation in two or three stages. The higher cortical centers were the least important things concerned as factors of safety.

Dr. Edward Martin of Philadelphia said that Dr. Bloodgood has so well expressed the general belief and the usual practice of men who had nearest their hearts the interest of the patients and the returning of them to their vocations in the most complete and perfect condition that there was not a great deal of room for suggestion or discussion, and yet there was one point to which perhaps he would take exception, and that was that the higher cortical centers were the least important ones as factors in safety of the patient. The ego, the individual aside from the physical, had an absolute dominating control over every function of the body and by no means the least important part of the attitude of absolute optimism on the part of the surgeon himself, his assistants, and all those professional people who came in contact with that patient. Many a time when the case was evenly balanced the victory had been won by that optimism and belief in recovery by which the patitnt had been properly influenced before and after the operation.

Dr. Harold J. Gibby of Pittston said that one of the most important points aside from the physical condition was the temperament of the individual. The individual who resisted the anesthetic, who was of a depressed nature, was sure she was going to die, was often a very poor subject. Another thing was the importance of diagnosis—to find out just how much had to be done and how much work could be done at the one sitting.

The Influence of Various Anesthetics in Determining Mortality.—Dr. George M. Laws of Philadelphia read this paper. He said that surgical anesthesia was easy to obtain with chloroform, more difficult with ether, and most difficult with nitrous oxide, and statistics showed that their relative safety was in reverse order. At the Hospital of the University of Pennsylvania nitrous oxide followed by ether had been the routine anesthetic for years and a continuance of the favorable results convinced them that ether pneumonia could be eliminated by proper application of this method. Whether or not a general anesthetic should be given when shock was present depended largely upon an accurate estimate of the psychic element. The horror of ether was one of the greatest obstacles to modern surgery as it led the patient to defer operation. Therefore an anesthetic which was not unpleasant to take had much to commend it. Ethyl chloride had about the same range of utility as nitrous oxide, but its mortality rate, which was distinctly higher than that of chloroform, made its use rarely justifiable. Nitrous oxide followed by ether given by the drop method overcame practically all the objections to ether alone.

Dr. William L. Estes of South Bethlehem said that he believed the principal thing in every anesthetic was the person who gave it—"the man behind the gun." This implied that the man or woman of experience would adapt as a rule the anesthetic and the quantity of anesthetic to the patient in hand. The next point in giving the anesthetic it seemed to him was the psychic state of

the patient. He believed that nephritis, especially the chronic kind, was not a contraindication to ether.

Dr. George W. Guthrie of Wilkes-Barre said he believed in ether and yet he was satisfied that the ultimate dangers of ether were sometimes overlooked. The drop method was the best method of giving ether.

How Long Should Patients Remain in Bed After Various Operations?—Dr. Robert T. Miller, Jr., of Pittsburgh read this paper. He said we could not establish any law or precedent that could be safely followed in deciding the question as to how long patients should be kept in bed after operation. It was necessary to eliminate all purposeless effort and have the patient concentrate his whole strength upon the problem of recuperation. This meant absolute rest in bed. This might be required for two days, two weeks, or two months. Exceptions to this were found in the case of elderly people as regards pneumonia and uremia, both of which conditions might be warded off by postural change.

The Prevention and Treatment of Complications in Gastrointestinal Surgery.—Dr. Donald Guthrie of Sayre said that the success in this work depended more upon strict attention to details which were often regarded by some surgeons as minor and unimportant rather than upon any unusual dexterity which might be displayed in the operating room. The results of the surgeon who operated upon another's diagnosis and who never saw his cases after operation could never be as good as those of the man who worked his cases carefully up for himself, who developed a simplified technique of his own, and who carefully watched and treated such cases during their convalescence. The most common complications after operation on the gastrointestinal tract in the order of their frequency were shock, acute dilatation of the stomach, pneumonia, adynamic ileus, embolism, fatty degeneration of the liver, and peritonitis. Important factors in preventing these complications were the development by the surgeon of a technique of his own in the availability of a competent anesthetist. In most of the well run operating rooms the giving of an anesthetic was entrusted to a nurse specially trained and not to the youngest interne, who might be more interested in the steps of the operation than in the patient. The man who had a permanent force in his operating room could do better work in all branches of surgery, especially gastrointestinal surgery.

Dr. William L. Rodman of Philadelphia said he was sure it would be much better for patients if the amount of anesthetic given were reduced after the peritoneal cavity had been opened. He had been in favor of female anesthetists for the past ten years because they were more timid and saw danger quicker than a man. However, he would like to know what would be the legal responsibility of the surgeon whose patient died on the table while the anesthetic was being given by a trained nurse. He did not think the diploma of a trained nurse allowed her to give poisons. The thing that had brought him his best results was the administration of morphine and atropine one hour before operation and the next best was postoperative lavage.

Dr. Charles H. Frazier of Philadelphia said in reference to the question which Dr. Rodman had brought up that he had consulted a lawyer prior to the employment of a female nurse anesthetist at the University Hospital and was assured by the lawyer that the hospital authorities were entirely justified in employing her and would not be liable for damages, providing they realized that in the employment of this special anesthetist they were doing it for the best interest of their patient. We should try to get a woman to give ether and ether alone. It seemed scarcely fair to a professional anesthetist to have cases brought in to her and have her instructed to give the anesthetic before she had had an opportunity to go over them. She should have a list of cases to be operated on the day before operation so that she might see the patient, inquire as to the nature of the operation to be performed, look into the history of the case, and make some examination perhaps of the heart or lungs before the patient was brought to the operating room.

Dr. John B. Roberts of Philadelphia said he believed that women did many things better than men, but he believed that all anesthetists should be those qualified to practise medicine; qualified to determine whether the patient had a good or bad heart, good or bad kidneys.

Dr. Charles S. Thomson of Scranton said that he did not think that all our troubles had ended with anesthetics when we had introduced nurses to administer them, but he thought that they were so far advanced, so much better than anything we had ever heretofore enjoyed that we were making real progress in handing over our anesthetics to trained nurses, that was to nurses who had been trained to give anesthetics.

Dr. George W. Guthrie of Wilkes-Barre said that, as to giving poisons, the nurse was authorized to give hypodermics of atropine and strychnine in the absence of the doctor, whereas the anesthetic was never given unless the doctor was present.

Dr. C. J. Cummings of Williamsport said he would not have it understood that a woman could give an anesthetic better than a doctor. He did not believe that should be accepted. As to the legal aspect of it, that was an entirely different thing which he did not think had ever been decided.

Dr. G. E. Shoemaker of Philadelphia emphasized what Dr. Cummings said and said in addition that this question was a practical one in our hospitals only and did not refer to the trained nurse in general practice giving anesthetics. We could not get our internes to take enough interest in anesthesia to do it right. Therefore somebody must be hired who would stay in the hospital one or two years solely to perform anesthesia.

Dr. J. C. Bloodgood of Baltimore, Md., said it was his feeling that anesthesia was the stepping-stone to surgery, that every surgeon who operated should have had an experience in anesthesia. There was no practical experience which taught the individual the physiology and the problems of physiology which were of the utmost importance to the surgeon in the treatment of respiration better than anesthesia. He thought that men who went into surgery should have their experience of anesthesia and he thought that the anesthesia in most of the clinics where it was possible should be given by the men who ultimately expected to go into surgery.

(To be continued.)

AMERICAN ASSOCIATION OF OBSTETRICIANS AND GYNECOLOGISTS

Twenty-Fourth Annual Meeting, Held in Louisville, Ky., September 26, 27 and 28, 1911.

(*Concluded from page* 845.)

The President, Dr. Herman E. Hayd of Buffalo, N. Y., in the Chair.

Cervical Fibroids.—Dr. Lewis F. Smead of Toledo said that fibroid tumors of the cervix and uterine body below the movable peritoneum had not received the attention to which the great technical difficulties of their removal entitled them. The subperitoneal variety were the most troublesome because of their immobility and the obliteration of landmarks caused by them. In fact, they belonged to a class by themselves. Fibroid tumors of the cervix were found in about 5 per cent. of all women who

had uterine fibroids. The tumors might arise in front of, behind, or at the side of the cervix, but the posterior growths were somewhat the most common. The physical characteristics of these tumors were not unusual, but the distortions of the pelvic organs, especially of the vagina and bladder, were common. The cervical tumors, because of their position and their immobility, were very likely to block the birth canal. Small fibroids on the anterior cervix, projecting into the base of the bladder, might simulate almost exactly the male prostate. The bladder was usually enormously elevated and enlarged by being stretched out over the tumor. The vagina was much elongated and crowded out of position. The rectum and vagina were much thinned by pressure atrophy. The ureters might be pushed up by a tumor or pulled up by adhesions. They might also be blocked by pressure or kinking. The rectum and sigmoid were raised up by tumors arising beneath them. One might avoid surprises and lack of preparation by a careful preoperative diagnosis of the relations of the tumors to the pelvis. The position of the upper end of the vagina was usually the key to the situation, and an examination under ether would often locate it. The operative treatment was radical, rarely palliative. The operative removal required the use of special operative maneuvers, such as bisection of the uterus and tumor, enucleation, and excision of a large wedge of the tumor or the classical side-to-side hysterectomy. The principle of the Doyen hysterectomy could often be employed with profit. The cavity left was very liable to infection from the rectum, and would usually have to be drained, although in some cases it might be obliterated and the abdomen closed.

Early Diagnosis of Ectopic Gestation with Report of Fourteen Cases Diagnosed and Operated Upon Previous to the Time of Rupture.—Dr. R. R. Huggins of Pittsburg believed that the time had arrived when the diagnosis should be made previous to the final rupture and collapse in at least 80 per cent. of the cases, provided a physician was called. When a woman whose menstrual period has been regular missed or went beyond her time for menstruation, she would suspect pregnancy. If a flow from the vagina began in a period varying from four or five days to three weeks after the regular time, continuing more or less regularly, accompanied by pains, periodic in character, located in the hypogastrium on either side, extrauterine pregnancy should at once be suspected by the physician, unless some other well-defined condition was present to account for it. The vaginal hemorrhage might be dark colored blood, coagulated at times; at others a blood-tinged leucorrhea; or in some instances bright red. It was sometimes described by the patient as being different from the normal menstrual flow and was therefore atypical. This hemorrhage was doubtless due to a partial separation of the ovum from its cyst wall, or to the separation of the decidua from the uterus. In 95 per cent. of the cases of ectopic pregnancy seen by him the history and local symptoms had overshadowed all others and seldom in the early weeks had there been present the usual general signs of pregnancy. It was true that this did not occur in every instance. In some cases there was no history of either pain or hemorrhage or flow of any kind, the first symptoms being those of sudden severe pain and collapse. Careful study of the history in fifty-two cases which had gone on to rupture in his own experience showed that in all but five there had been some irregularity of the normal flow and pain before the final rupture and collapse.

Interstitial Pregnancy.—Dr. N. Stone Scott of Cleveland stated that there were three subdivisions. First was external interstitial pregnancy, the only one known until recently, but which had been much more frequently observed within the last few years. It was attended with danger, because rupture usually took place into the abdomen before the sixth month. The condition should be treated as a case of ordinary tubal pregnancy. Middle interstitial pregnancy was rare, only four cases having been reported. Internal interstitial pregnancy was frequently overlooked. The use of the curette was the etiological factor in the production of many of them. There were two varieties: The first one of these aborted into the uterus with spontaneous recovery. So-called false perforations of the uterus were frequently interstitial pregnancies. A number of illustrative cases have been reported lately. The second varity began as an interstitial pregnancy, developed into the uterus, and terminated normally. The report of his own case was the first one on record.

Dr. James F. Baldwin of Columbus stated that several years ago at a meeting held in Louisville he read a paper on the same subject, reporting six cases in which he had made a diagnosis of ectopic pregnancy before rupture and operated. At a meeting of the American Medical Association, held at Atlanta, Ga., in 1896, four years before that, during a discussion in the obstetrical section he reported five cases in which he made a diagnosis of ectopic pregnancy before rupture, and took the ground that the essayist had done to-day, that the diagnosis could be made before rupture. At that time no one present had ever made the diagnosis before rupture and operated. Dr. Price of Philadelphia reported one case in which he made a diagnosis; rupture occurred that night; he operated on the woman the next morning, and verified his diagnosis.

Dr. Charles N. Smith of Toledo said that the chief obstacle to early diagnosis in extrauterine pregnancy was the fact that a patient who was not suffering continuously or seriously did not consult a physician until rupture had taken place. If one would listen to the history and analyze it and the local symptoms, as the writer of the paper had said, there could be but little excuse for failure to make a diagnosis in these cases prior to rupture.

Dr. Roland E. Skeel of Cleveland said that many practitioners favored certain treatment in cases of ectopic pregnancy. Surgeons need not break their necks to operate because the primary hemorrhage would probably cease, and if it did they must not delay operation until day after to-morrow, because another vessel might rupture, and they should operate as promtly as possible.

Dr. E. Gustav Zinke of Cincinnati stated that the pathology of ectopic gestation was vast, and he who had not grasped it would fail to diagnosticate cases of ectopic pregnancy or would mistake them for something else. Tubal pregnancy, with normal genitalia, was an entirely different thing from an ectopic gestation occurring in a patient with a pathological condition in the tube, the ovary, and uterus. The symptoms of a tubal abortion were entirely different from those in a case of tubal rupture. In one case, the tubal abortion, the symptoms were not alarming, and the woman might recover, and the diagnosis might remain in doubt; while a case of tubal rupture, with an otherwise normal pelvic cavity, was so typical that no man could mistake it for anything else. Again, there were ectopic gestations which were strictly tubal and remained so from the beginning to the end, and they were the cases that were comparatively free from some symptoms and went on to the end of term with a living fetus, and they were easily removed because they were more or less pedunculated. No adhesions had taken place. In another case one might have tubal rupture and the neighboring structures might become involved, the intestines and omentum, the pelvic organs, and the pelvic peritoneum, and the fetus would go to the sixth or the seventh month, when it would die from lack of nutrition and become encysted. Then there were those cases in which the fetus would undergo solidification, etc.

Dr. Hugo O. Pantzer of Indianapolis stated he would like to add another symptom to the signs and symptoms given by Dr. Huggins which was invariably present, namely, a pulsating tumefaction on one side and not on the other. In rare instances this was attended with marked congestion or with tubal inflammation.

Dr. Charles L. Bonifield of Cincinnati stated that a great many women with ectopic gestation would get well without operation. It was the experience of every operator who had operated on these cases that, after he had examined the specimen, he had wished he had left the patient alone, that nature would have cured her.

Dr. William H. Wathen of Louisville stated that, in looking over his cases, seen in private practice and in consultation, he found he had had approximately 150 of these cases, and of that number had seen but one patient who bled to death, and that occurred about twenty years ago when he was called and reached the patient just as a secondary hemorrhage had caused her death. These patients would not bleed to death if the rupture was between the folds of the broad ligament, and seldom or never if it was a tubal abortion. They might have a rupture. They might have a rupture through the tube into the peritoneal cavity, provided a large vessel had ruptured He thought if we took all the cases of ectopic pregnancy in which rupture had taken place during the last twelve months we would find that not one out of twenty-five had bled to death from secondary hemorrhage.

Dr. Walter B. Dorsett of St. Louis recalled a woman who, in a female hospital of which he had charge, ran up to the third floor on account of plastering that was going on below, fell, and died suddenly from a ruptured ectopic pregnancy. She had not been in the hospital more than two or three hours. The body was taken to the dead house, and a post-mortem examination disclosed the abdomen full of blood:. She had bled to death. This case occurred in 1887. These women would bleed to death more frequently than had been stated by Dr. Wathen.

Dr. A. B. Miller of Syracuse said the general practitioner in many instances was not called sufficiently early to make a diagnosis, and we had heretofore attributed the late diagnoses in these cases to want of knowledge or education on his part, but the general practitioner was not so much to blame. We saw cases of our own where there had not been one symptom suggestive of ectopic pregnancy. These patients expressed themselves as feeling perfectly well, but in six hours thereafter they became desperately ill, showing that rupture had taken place. We could not always make an absolute diagnosis by the symptoms and physical findings.

Dr. D. C. Moriarty of Saratoga Springs believed the diagnosis of ectopic pregnancy was very much the same as in tuberculosis. If one made a diagnosis of tuberculosis early enough to save the life of the patient, he would have to make the diagnosis in 20 per cent. where it did not exist, consequently he thought it was well to operate on these cases of ectopic pregnancy early.

Dr. Miles F. Porter of Fort Wayne said it was not true, as Dr. Wathen had intimated, that none of these women died of hemorrhage. All knew better than that. He would undertake to say that he could find fifty men who would be able to operate on these cases practically as they came to them, and they would have a less death rate than another fifty men who practised the finesse referred to, and that was the reason he was not in favor of this extreme diagnostic finesse.

Dr. William H. Humiston of Cleveland said he had had four cases in his experience on which he had had the opportunity of operating before rupture. As a rule, these patients did not consult a physician unless they were very nervous and were in pain, and that was why a great many of them were not diagnosed before rupture.

Cesarean Section.—Dr. William H. Humiston of Cleveland reported a case of multiple cesarean section, in which he resorted to both the high and low operations, and exhibited photographs of the mother and child.

A Study of a Pseudo-Hermaphrodite.—Dr. H. S. Crossen of St. Louis presented a lantern slide study of a pseudo-hermaphrodite. This individual had dressed and lived as a female forty-two years but, as investigation demonstrated, was undoubtedly a male. The mistaken idea as to sex under which this patient had lived since infancy was due to a condition of hypospadias. The deformed male external genitals presented considerable resemblance to the female external genitalia. The case emphasized forcibly the fact that extreme care should be exercised to determine correctly the sex in every case of anomaly of the genitals in the newborn. The great majority of pseudo-hermaphrodites were really males, hence the rule was that in cases where the sex could not be positively determined in infancy the child should be treated as a male until unmistakable evidence of the opposite sex appeared.

Radiographic Diagnosis of Gastric and Duodenal Lesions.—Dr. Lewis Gregory Cole of New York City, by invitation, presented a radiographic study of motor phenomena of the pyloric end of the stomach and duodenum with a view to the early diagnosis of carcinoma, ulcers, and adhesions in this region, which was illustrated by numerous lantern slides and cinematographic films. He said anatomically and physiologically the first portion of the duodenum had always been considered a part of the small intestine, but normally it was dilated into a triangular cap which surmounted the pylorus and corresponded in size and shape with the stomach, and had absolutely no resemblance to the small intestine. Its motor phenomena corresponded with that of the gastric peristalsis, and it was absolutely free from the small, rapid, peristaltic contractions of the remaining portion of the duodenum. It was probable that the chyme in this portion had not yet been neutralized by the intestinal and pancreatic secretions. This might account for the fact that 90 per cent. of duodenal ulcers occurred in this portion. Personally, he considered the pyloric sphincter as a butler guarding the entrance to the intestines and allowing only that food that was recognized as properly prepared to be served to the intestine, and closing the door to prevent it from falling back into the stomach during diastole. He believed that the relative strength of the butler (the pyloric sphincter) to the cook in the kitchen (the peristaltic contraction of the stomach) was one of the most important factors in functional derangements of the gastrointestinal tract. Dr. Cole projected on the screen four radiograms which showed the thumb marks of carcinoma before the patient was fairly in the grip of the deadly enemy. The diagnosis of gastric carcinoma at an early stage was now accomplished in a very large percentage of cases, and the radiologist was justified either in making a negative diagnosis or stating with certainty that there was either a benign or malignant lesion which required an immediate operation.

Dr. Charles A. L. Reed of Cincinnati followed with remarks on displacements of the stomach and colon, their clinical significance, diagnostic features, and surgical treatment with report of cases illustrated by lantern slides.

Drainage: The Essential Element in the Surgery of the Biliary Tract.—Dr. Charles N. Smith of Toledo stated that cholecystectomy formerly was considered advisable, even necessary, in practically every case of hydrops and of empyema. In present-day practice, however, many a gallbladder cut out from the biliary circuit and rendered practically functionless by a calculus or an inflammatory block in the cystic duct could be restored anatomically and functionally by a drainage operation.

Neither hydrops nor empyema necessarily called for the removal of the gallbladder. In those cases of hydrops resulting from occlusion of the cystic duct by a calculus the gallbladder generally could be restored to usefulness by removal of the stone and subsequent drainage, provided that the bladder walls had not been rendered extremely thin from overdistension by the imprisoned mucus. In practically all of those cases in which the extraction of the calculus was followed by the escape of bile from the duct the gallbladder should be drained rather than removed. In a large proportion of the cases of empyema the gallbladder could be saved and its function restored by drainage. The more acute the process and the shorter its duration the greater the prospect of cure. When suppuration occurred in a gallbladder which previously had been obstructed, the obstruction having existed for a long time, the performance of a cholecystectomy became a necessary procedure. In several instances of perforation of a suppurating gallbladder he had removed the calculus obstructing the cystic duct, drained the gallbladder through the perforation, and had a complete restoration of function in every case. Drainage was recognized as the one dependable procedure in the treatment of localized infections, and it must be looked upon as the essential element in the surgery of the gallbladder and ducts. Natural drainage through the common duct into the intestine could not be depended on as a curative measure even in cases of mild infection. The distal opening of the common duct at the summit of the duodenal biliary papilla averaged, according to Opie, but one-tenth of an inch in diameter. While in its healthy state it afforded free exit for normal bile and pancreatic fluid, it was subject to encroachment upon its lumen by inflammatory swelling, greatly interfering with the rapidity and volume of the discharge through the orifice. The tenacious mucus so abundantly secreted during inflammation of the gallbladder served to delay the onward flow and escape of bile and of itself became an obstructive agent. When an infection involved both the ducts and the gallbladder the mechanical interference from the swelling of the mucosa and the increased viscosity of the bile from the added mucus resulted in a decided hindrance, if not a positive obstruction, to the escape of bile into the intestine. As drainage was essential to the restoration of normal conditions within an infected biliary tract, and as it could not be attained through the natural channels with any degree of certainty, it devolved on surgery to establish and sufficiently maintain that drainage.

President's Address.—Dr. Herman E. Hayd of Buffalo reviewed the early scientific work of the association and referred to some of the epoch-making contributions of the members. He spoke of the evolution, growth, and development of the association. He made reference very feelingly to those fellows who had died during the year, namely, Drs. Montgomery Linville, George E. Goodfellow, Manning Simons, William Warren Potter, C. C. Frederick, and Joseph Price. The speaker then reviewed the progress that had been made in the practice of obstetrics, in gynecology, and pelvic surgery, and said that during the past quarter of a century many great surgical questions and pathological problems had been settled. The treatment of displacements of the uterus was now definite and established. Plastic operations upon the cervix and perineum had been wonderfully successful and satisfactory. Ovariotomy, either for cystic or solid tumors of the ovary, had reached perfection in its technical management. The successful management of extrauterine pregnancy was a crowning tribute to specialized effort. The diseases of the liver and pancreas had been assiduously studied, and the results of timely and well-directed surgery were most satisfactory and encouraging. Diseases of the bladder, ureters, and pelvis of the kidneys had received the closest study and investigation by the modern specialist, but this class of work could only be carried on successfully by men especially trained and who had the time and desire to specialize in this careful and patient line of surgery. The speaker reviewed the work that had been done with reference to dealing with cancer, hernia, and postoperative adhesions. The splendid results of modern medicine, and especially surgery and midwifery, had been in a very great measure accomplished through the efforts and assistance of the trained nurse, and no address would be complete before a body of men whose successful work was so dependent upon these conscientious and devoted women unless it were illuminated by kind and appreciative reference to their services.

The Obese Abdominal Wall.—Dr. Francis Reder of St. Louis stated that a large accumulation of fat upon the abdominal wall, such as was often found in women, was a distinct handicap to the surgeon in his work in removing a small fibroid tumor in an atrophic uterus, a retrocecal appendix, or a small gallbladder tucked away in a deep fossa, with a stone in the cystic duct, or, still worse, a stone in the common duct. To obviate to some extent the embarrassment caused by excessive fat, he had followed during abdominal operations the suggestion of Dr. Kelly, who advised the excision of enough of the obese wall to facilitate intraabdominal work, and from his limited experience gleaned from operations upon five patients, where masses of fat were removed, the intraabdominal work was rendered less difficult; but he could also say that in few of the cases this fat caused considerable trouble which was induced by a late section. It did not require any particular skill to cut enough of the fat away about the field of operation to get a sufficient amount of room for easier work; but it did require some knowledge to so ablate these masses of fat that no untoward consequences might arise. To prevent any postoperative sequelæ, a wedge-shaped mass of fat should be removed, the two incisions converging into one upon the fascial layer. This left no undermined surface as a receptacle for secretions. It did not matter how long the incision was, provided there was no extensive undermining of the fat layer. To be as accurate as possible in excising a wedge-shaped piece of fat, he had found it of service to first carry the straight incision across the abdomen down to the fascia, this incision disclosing the thickness of the fat. By placing the left hand into the incision and against the fat wall, he was able to guide more accurately the right hand in making the upper and lower flaps. After the ablation of the fat had been accomplished, the wound was covered with hot saline cloths, while the intraabdominal work was being conducted. Fat removal was only to be recommended, however, when the mass of fat was a distinct obstacle to the intraabdominal work.

Factors Entering into the Mortality of Acute Intestinal (Mechanical) Obstruction.—Dr. John Young Brown of St. Louis said that, in considering the factors entering into the high mortality of acute intestinal obstruction, we must place at the head of the list late operation; second, treatment received before operation; third, the technique and time of the operation itself; fourth, the after treatment. If we could impress upon those who first see such cases that delay meant disaster, and that a low mortality could only be gotten by an early operation, much good could be accomplished. However, this was not always possible. Not infrequently, although the condition was recognized by the attending physician, the family would refuse to consent to an immediate operation, or it might be possible to get at once a surgeon competent to do this work. This being the case, it became the duty of those who taught to call attention to the harmful nonoperable measures which were commonly employed, with the mistaken idea that they were beneficial. Foremost among

such remedies he might mention cathartics. The symptoms in any case argued eloquently against their use. Nature invariably warned, by the retrograde peristalsis and the persistent vomiting, that she was making an effort to relieve the distended bowel above the block. Cathartics were as harmful in such cases as diuretics would be in a case of retention of urine due to an impermeable urethral stricture; yet we rarely saw a case come to operation that had not been given cathartics varying in strength from calomel to croton oil. If gastric lavage was used in the same routine manner, the profound toxemias found in the cases of three and four days' duration would be far more infrequent. Morphine was another drug the use of which could not be too strongly condemned. Regarding operations undertaken for the relief of such conditions, one must carefully guard against certain errors of omission and commission which added to their danger. As all such operations had for their purpose the relief of the block and second the removal from the bowel of as much as possible of its highly toxic septic contents, all such operations should be preceded by a careful washing of the stomach. Much toxic material could be removed in this manner and the danger of fecal drowning during the administration of the anesthetic was greatly lessened. The administration of the anesthetic should always be entrusted to a careful anesthetist. The operation should be executed as rapidly as possible. When the abdomen was opened, if the bowels were greatly distended, it was far safer to puncture in several places, liberating the gases and draining the bowel. Such small punctures could be rapidly closed with purse-string sutures. It was bad practice to forcibly handle a distended bowel. In cases where resection was necessary, it was of prime importance to carefully drain the bowel above the block. The after-treatment of such cases should consist of frequent stomach washing, the avoidance of opiates, and the use of salt solution, both by the rectum and under the skin.

Personal Observations on Cancer.—Dr. J. GARLAND SHERRILL of Louisville stated that in making a study of the cases of cancer occurring in his private practice he had been able to follow 208 of these cases and trace them to the present time. Among these cases different portions of the body were affected. Of 19 abdominal operations 11 patients were living, 5 past the third year limit, while others had died in from 12 to 18 months. Of 12 vaginal operations, 4 patients were living from 3 to 12 years after the operation; 8 had recurrence, dying within 18 months. Experimental work would seem to show that true cancer tumors might be produced by inoculation, as Langenbeck successfully inoculated a dog. This fact, studied in connection with other reports, and the further fact that metastasis occurred in cases where local disease seemed to be entirely eradicated by operation tended to lead one to the belief that carcinoma was due to an actively proliferating poison or entity; in other words, a living organism. Trauma and irritation were important factors in the determination of the site of a malignant neoplasm. His cases showed 8 per cent. in which trauma was noted, and 18 per cent. in which irritation was a factor. The results in his limited number of cases showed very readily the improvement in end results when radical surgical treatment was applied early. This was the experience of practically all observers. To obtain the best results the patient must, first, apply early for treatment: second, all suspicious growths should be removed. Keen and others went so far as to recommend the removal of all superficial growths lest they became malignant. The serum treatment of cancer had been disappointing. He had used the ascitic fluid of one patient, which was injected into her own tissues, with no marked benefit, although the disease seemed not to progress during the time of its employment. Fulguration had not accomplished much, nor had the *x*-ray done more than the knife or cautery could accomplish in a more thorough and certain way. While it was true that a considerable number of cases of cancer were curable by radical surgical treatment, in a much larger percentage of cases they were hopeless before they came under observation. In view of the supposed infectious character of this disease, it was reasonable to urge the attendants of a cancer patient to avoid allowing the secretions to come in contact with the unbroken surface and to use the most stringent measures of cleanliness in the care of those patients. The room in which a cancer patient lived should be carefully disinfected. Such measures could result in no harm and might be of benefit in the prevention of the spread of the disease.

Sterilized Animal Membranes in Surgery.—Dr. ROBERT T. MORRIS of New York stated that for some years he had been experimenting with the absorbable animal membranes in surgery, and now and then had found some point which he thought was new in connection with this work. One case worthy of report was that of a young man, who, at Princeton, in riding down a steep hill on his bicycle, met an automobile coming up, turned aside suddenly into a bank, and the handle of the bar of his bicycle tore five holes in the ileum. In this case there was so much contusion that he did not know where to resect. He washed out the blood and fecal matter, and decided temporarily to cover each opening with the Cargile membrane in a sort of mechanical way until the patient passed the period of shock, and then to consider the possibility of excision of the bowel if the young man should live. The loops of perforated bowel were thrown about a small central drain, and a large dressing applied, and the young man not only lived, but the speaker did not do any excision of bowel, and that patient was walking in thirty days without any fistula. That, he presumes, was due to the use of the Cargile membrane and to nothing else. He had not anticipated any such result in this case. It was a temporary procedure with a dying boy. Another point he had noticed with the Cargile membrane was that sometimes it did not undergo absorption rapidly. In an automobile accident, the patient having sustained a depressed fracture of the skull, he elevated the skull, separated the adhesions, and placed a large segment of Cargile membrane between the dura and the cranium. In this case there was occasion to do an operation some eight months subsequently for some remaining adhesions, and this membrane had not undergone any change whatsoever so far as he could observe. It remained perfectly free and loose. It had prevented the formation of adhesions over the area he dressed and there were some supplemental adhesions about the periphery. This was an odd thing, and he did not know how to account for it. In many cases he had used the membrane for the prevention of recurrence of peritoneal adhesions as perhaps the favorite resource. In most cases now in which he had occasion to separate extensive peritoneal adhesions he depended upon placing a sheet of this sterilized animal membrane over the area from which adhesions had been separated for the purpose of preventing a mechanical obstacle to the recurrence of adhesions.

The Relation We Bear to Our Patients and What Use Shall We Make of Our Knowledge of the Evil Effects of Venereal Disease.—Dr. ALBERT VANDERVEER of Albany referred to the work early done in the life of the association regarding pus in the pelvis, and especially to the work of the late Dr. Joseph Price, and the earnestness with which the Fellows investigated this subject, a large percentage of the cases being directly traceable to gonorrheal infection. He made a plea for placing before the public more clearly our knowledge of syphilis and gonorrhea. In this manner he believed much suffering would be prevented. Parents were desirous of obtaining information on this subject. Young people were

entitled to know more regarding their reproductive organs and the evils that may follow infectious diseases. While much was being accomplished at the present time in the literature presented by our able representative publications, yet he felt that as a profession we could accomplish much more than we had in the past.

Methods of Skin Sterilization.—Dr. John E. Cannady of Charleston, W. Va., reviewed the history of the iodine methods of skin sterilization. The method he employed was the fractional one. The skin was carefully shaved and cleansed with soap, cotton sponges, and hot water, followed by alcohol. After the skin had dried it was painted with a 2 per cent. solution of iodine and alcohol. This was done the evening of the day before the operation, and when the skin had dried a sterile gauze dressing was applied. Early the next morning the skin of the operation site was again painted and the dressing reapplied. Lastly, while the patient was being anesthetized the skin was painted for the third time. The results had been uniformly good. The scrubbing brush and the bichloride compress were no longer used on the patient. The laboratory findings of Kinnaman showed that iodine was at least one hundred times more powerful a bactericidal agent than bichloride.

Some Factors in Operative Technique and Management Which Make for Success or Failure.—Dr. Walter B. Chase of Brooklyn contributed a paper on this subject in which he emphasized the following points: (1) Ascertain with all possible accuracy any variation from the normal standards of health, functional or organic. This included a precise knowledge of any involvement due to coexisting disease of the circulatory, respiratory, renal, hepatic, digestive, and nervous systems, apart from the special surgical aspect of the case. (2) That the power of hereditary longevity, as related to existence, so often otherwise unexplainable on the chances of recovery after operation, could not be gainsaid. Seek out with scrupulous care the previous history of the patient suffering from serious disease or accident. If such had recovered with little or no impairment, other things being equal, they were safe subjects for operations. He had recently had a most remarkable demonstration of this truth not yet reported where adverse circumstances would ordinarily have forbidden operative interference. (3) The surroundings of the patient must be inquired into. If there was vital impairment, save in imperative cases, one should take all the time needed, in which there should be the best attainable explanation of the lowered vitality of the patient. (4) Too many specialists, having little or no knowledge as general practitioners, fell into the grievous error of operating for appendicitis when the ailment was typhoid fever, for supposed intestinal obstruction in the presence of fecal impaction, or for cholelithiasis where only cholecystitis was present. It was safer and wiser to admit a lack of knowledge on diagnostic points than to act on insufficient data. (5) The emotional nature could not be ignored. The influence of hope and fear, the most powerful motives in the human heart, must be reckoned with. They might be potiential in the domain of surgical procedure. The confidence of the patient must be had in full measure, not in diagnosis alone, but as related to results. These neurotic cases must be saved from the depressing influence of needless delay, when decision had been made for operation. Their knowledge of unfavorable factors must be guarded and self-reliance strengthened. Here might be a legitimate field for the hypnotist. (6) The evil of procrastination on the part of the operator when the plainest evidence demanded immediate operation was a matter of profound regret and was open to severe criticism. There was an imperative need of skilled anesthetists. If the mortality resulting wholly or in part from shock and hypernarcosis from the excessive and unskillful use of anesthetics were known and appreciated, there would be inaugurated new methods in hospitals and private operations, and college and hospital teaching would undergo radical changes. No matter who the operator or where his work was done, those entrusted with the administration of the anesthetic should be the best and not those least qualified for such important work. When such standards of requirement were enforced fewer deaths from causes not well defined would mar hospital and private statistics.

Prevention of Shock.—Dr. J. H. Carstens of Detroit contributed a paper on this subject in which he drew the following conclusions: (1) By simplicity and tact in management before operation much shock could be prevented. (2) The surgeon should have everything ready in the operating room, and the anesthetic should be started immediately. (3) All the necessary ligatures and instruments should be at hand, so that there need be no delay during the operation. (4) One should analyze the case thoroughly beforehand so that he might know exactly what he was going to do, and how he was going to do it, and what complications might arise. (5) Two quarts of salt solution in the form of an enema should be given, or given hypodermically as soon as the operation was finished. (6) The patient should be kept free from pain for twenty-four hours after the operation.

Officers.—The following officers were elected for the ensuing year: *President*, Dr. X. O. Werder, Pittsburgh, Pa.; *First Vice-President*, Dr. Louis Frank, Louisville, Ky.; *Second Vice-President*, Dr. Magnus A. Tate, Cincinnati, Ohio; *Secretary*, Dr. E. Gustav Zinke, Cincinnati, Ohio; *Treasurer*, Dr. Herman E. Hayd, Buffalo, N. Y. Toledo, Ohio, was selected as the place for holding the next annual meeting; time, September 17, 18, and 19, 1912.

MEDICAL SECTION OF THE AMERICAN LIFE CONVENTION.

Stated Meeting, Held at Pittsburgh, Pa., September 20, 1911.

(Special report to the Medical Record.)

(*Concluded from page* 893.)

The President, Dr. Amand Ravold of St. Louis in the Chair.

Blood Pressure and Prognosis.—Dr. Henry Wireman Cook of Minneapolis, Minn., Medical Director Northwestern National Insurance Company, presented this paper which was read by Dr. S. H. Baxter, Assistant Medical Director Northwestern National Life Insurance Company, Minneapolis, Minn. (See page 959.)

Dr. Fred M. Hodges of Richmond, Va., Assistant Medical Director South Atlantic Life Insurance Company, said that they all knew that Dr. Cook was a pioneer in the study of the sphygmomanometer. There was a widespread belief that high blood pressure readings meant disease; but in nearly every instance manifestations of the underlying conditions might not have been made out without the use of the sphygmomanometer; in many instances an accurate diagnosis and prognosis could not be made without the use of this instrument. When attempting to make a standard low and high blood pressure, there were certain elements that must be taken into consideration, such as the occupation of the applicant. The few millimeters of pressure in a laborer did not mean the same as the same number in an office man. A blood pressure of 105 might be very low and one of 145 might be very high. All knew that an increase in the blood pressure meant one or two things. Where there was an increased amount of blood to be handled by the heart, where there was an increased vascular resistance either peripherally or through the splanchnic area, or where there was valvular disease and obstruction to the flow of

blood, or where there was a leakage, a backing up of blood into the cardiac chambers, that all meant that there was an increased amount of energy to be expended and caused an hypertrophy of the musculature of the heart. Again where there was an increased vascular resistance both peripherally and in the splanchnic area, such as one found in cases of nephritis, especially in the interstitial variety, and in patients with arterio-sclerosis and syphilis, there were indications of early vascular disease. There should also be considered in this connection lead poisoning and the gouty tendency. Many application blanks contained the question: "Is the pulse hard or soft or fibrous and full?" Many local examiners reported in the affirmative and further stated that there was an accentuated second sound. The question was commonly asked: "What were the diseases commonly overlooked?" Those that gave a high mortality, and in these the sphygmomanometer in every instance would disclose that further investigations should be made. Chronic interstitial nephritis was the disease that was the most important to them. If the blood pressure readings were high, and if the microscopical examination of the twenty-four hours urine revealed albumin, a diagnosis of chronic interstitial nephritis was made. But when a local examiner examined such a case he would rarely report the existence of an hypertrophied heart or an accentuated second sound; he would not be doing the refined tests called for. As a result many of these cases were overlooked. Dr. Hodges recalled three cases that were above the average; in all the blood pressure was above 108 and in one case it was 210. There was no suspicion that there was anything wrong with these patients aside from the blood pressure readings. In tuberculosis they had the family history, the loss in weight, or something to tell of some impairment. In chronic interstitial nephritis there was the history of headaches; otherwise nothing that pointed to anything being wrong with the patient. Instances of hypertrophied heart were rarely reported. In many of these cases the blood pressure readings would aid the examiner very much. In some cases of autointoxication where an examination of the urine would show indican or an oxaluria, an examination of the blood pressure would cause them to make a urinary analysis. Many cases of syphilis gave no other signs or symptoms of a previous infection except what was found in the blood pressure readings. Dr. Hodges recalled three cases in which the blood pressure readings varied from 166 to 174 millimeters of mercury. The examiner could find no reason for this blood pressure. These people were all declined. Two years ago an individual applied for insurance; he also asked to have Ehrlich's 606 administered. He had no arteriosclerosis and there was but a slight amount of increase in the blood pressure readings. In such a case the increase in the mortality would be higher because of the predisposition to other diseases which might follow. These cases were not often reported by the examining physician. In considering the methods employed in determining the blood pressure, Dr. Hodges said that the auscultatory was the easiest to apply and more information could be thus obtained than in the palpatory method. In the sphygmomanometer they possessed the best instrument for making diagnoses and prognoses. It was an instrument that gave them knowledge of the condition of the cardiovascular system which could not otherwise be obtained; this instrument would help them especially in the substandard cases; it was an instrument easy of interpretation and placed cardiac and renal affections upon the same mechanical basis as the sulphophenol test had placed kidney affections.

Dr. Amand Ravold of St. Louis, Mo., said that all wanted to know the best form of sphygmomanometer to use; what was the best? Any instrument that must be tested every time before using, that must be brought back and tested again, was valueless. He paid $25.00 for an instrument; in one instance it registered 115 millimeters of mercury, but his finger told him there was a mistake. Another instrument used on the same case showed 137 millimeters of mercury. He asked of what use were such instruments. An instrument was needed which would show the blood pressure accurately, one that could be relied upon.

Dr. Alexander M. Campbell of Grand Rapids, Mich. Preferred Life Insurance Company, asked how long one would live with a persistent high tension. He had had patients under observation who had persistently carried a blood pressure of from 200 to 225 millimeters of mercury, and he had found it difficult to say how long these patients would live. This, he thought, was a very important subject for their consideration. There was a desirability of a uniform instrument for use in all companies; some instrument should be made and accepted for use by all insurance companies. On every blank furnished the medical examiner he believed there should be the question: "Are you familiar with blood pressure instruments and are you willing to make yourself familiar with them?"

Nervous Diseases as Applied to Life Insurance.—Dr. John S. Turner, Medical Director of the Southland Life Insurance Company, presented this paper. He said that the relation of nervous diseases to life insurance had been more or less neglected in the past. The importance of the subject was very evident when they considered the rapidity with which these diseases were increasing over the entire civilized world and that the rate of restoration had not kept pace with the rapid increase. Too often the general practitioner and local medical examiner were incapable of diagnosing these diseases in their incipiency, and for this reason the medical director should devote some special attention to this subject. The statistics upon which Dr. Turner based his observations on the increase and curability of cancer were those of New York State, as these had been kept more carefully than elsewhere in this country, although what other statistics were available seemed to show a like increase throughout the country. It was stated that at this time New York State had 362.3 insane persons for each 100,000 general population and one insane male for each 287 of the male population. Thirty-three per cent. of this insanity was due to alcoholism among males and 10 per cent. among females. Paresis was the next great etiological factor, representing 25 per cent. of all deaths. Heredity played a most important rôle in the etiology, representing about 35 per cent. in males and a higher percentage in females. In all mental troubles there was a train of premonitory symptoms that if properly interpreted would have informed the physican that a crisis would ultimately develop. Likewise in purely nervous diseases there were well-marked signposts that if observed would keep many examiners off the rocks of well-deserved criticism from the home office. A pure neurosis was frequently overlooked by the examiner unless the patient was honest enough to tell the examiner of the existence of such trouble. The psychoneuroses were not likely to be overlooked by the most ordinary examiner. In all cases where the applicant gave a history of insanity in the family it was well for the examiner to go carefully over the applicant and secure a full history of any stigmata, physical or psychical, which might be present at the time or which might have been present in the past. He should find out if the applicant has suffered from periods of undue depression, followed by a state of exhilaration or hilarity, whether hysteria had been suspected or manifested, if illusions, delusion, or hallucinations had been exhibited even in mild form, if the applicant had peculiar views particularly of a moral or religious nature. If one

or more of these manifestations were present in a person of marked neurotic tendency and over thirty-five years of age it was well to be cautious about accepting him or her for a long contract, and it was safer to leave such persons entirely alone. In such persons they might expect ultimately mania, melancholia, impulsive or borderland insanity, psychastenia, paranoia, or circular insanity. It did not follow that because mania and melancholia were functional diseases and frequently curable their victims were desirable as life insurance risks. About 75 per cent. of all cases of mania made good recoveries but there was a marked tendency to recurrence, while about 65 per cent. of the cases of melancholia recovered with a decided tendency to recurrences. Mental paresis was a most dangerous disease, particularly so to the life insurance companies because of the delusion of great wealth or business acumen, and the tendency to expand in a business way, and because of the uncertainty of symptoms and the tardy progress of the disease, and third because of the certainty of a fatal termination. Some of the early symptoms which should arouse suspicion were twitching or nervous irritation about various parts of the body, particularly the face, nose, and eyes; parasthesia of various parts of the body; hyperesthesia; irregular pupils; impairment of reflexes; clumsy gait; Jacksonian epilepsy; change in disposition, soon followed by excesses, failure of memory, grandiose delusions. A history of alcoholism or syphilis was frequent in these cases. Subjects of this class were apt to obtain large policies during the incipiency of their disease. Dementia needed only to be mentioned as all examiners recognized this form of insanity and the same was true of idiocy. Pellagra was becoming of importance in the South and it seemed probable that sooner or later other localities would have a knowledge of this disease forced upon them. At this time it was safe to warn all examiners to beware of an undiagnosed skin disease, insignificant though it might seem. While the courts of the country refused to recognize impulsive insanity as a disease the medical profession was bound to do so. This disease imght be continuous or paroxysmal, functional or organic. Kleptomaniacs and pyromaniacs belonged to this class and also dipsomaniacs, oniomaniacs, and demonomaniacs. They were most dangerous because many of them were suicides. Borderland insanity, usually organic, chronic and incurable, was seen in persons regarded as illy balanced. Heredity usually furnished a basis for this instability. It could be recognized in the harmless eccentric character to be found in every neighborhood. Many of these cases took to the excessive use of alcohol, narcotics, or other drugs. Persons of this type being of idiopathic, unstable, nervous organization usually succumbed early to some intedcurrent or exhausting disease. For that reason they were extrahazardous as life insurance risks. Psychasthenia was observed especially at the epochal periods of life. These subjects were exceedingly impressionable and easily fell prey to suggestions of evil which crystallized into delusions. This form of insanity was prevalent among women at the epochal periods of life and therefore women between the ages of 38 and 45 were not good risks for life insurance. Toxic mania, including the use of morphine and the entire list of narcotic and hypnotic drugs, was a condition the examiner must be mindful of. No medical examiner would deliberately recommend one of this class as a standard risk for a life insurance company but symptoms might be overlooked. In this class of cases there were three classes of symptoms—motor, sensory, and vasomotor. The motor symptoms included muscular, cardiac, and visceral weakness, incoordination, tremor, and disturbances of ocular accommodation. Some of the sensory were superficial or deep anesthesias, hyperesthesias, or parasthesias. The vasomotor were diminution of the secretions of the mouth and throat, and of the gastric and pancreatic juices, menstrual flow and urine. Gastrointestinal disturbances and albuminuria were often present. The skin was often cold and wet with a profuse perspiration. Other marked symptoms were the cachexia of the skin, tachycardia, and physical inactivity manifested by loss of memory, etc. Paranoiacs were extrahazardous as insurance risks from several standpoints; (1) They were so taken up with their delusions that they were usually improvident. (2) Believing that they were being persecuted by their neighbors they were often embroiled in personal encounters. (3) As a rule they were short lived, having but poor resisting powers to withstand degenerative and exhaustive diseases. Circular insanity was a form of insanity in which the subject might be accepted by an examiner not fully informed. The attack began with a characteristically acute maniacal explosion which gradually shaded into a distinct attack of melancholia with all its stuporous features from which recovery took place within a few weeks or months. Then a perfectly lucid interval of several months might intervene, when the patient again fell into a maniacal attack and the cycle repeated itself. In these cases the importance of a thorough knowledge of the personal and family history was made manifest and also the importance of a full and complete inspection report. In regard to locomotor ataxia, the most important of all neuroses, the writer said that this was a condition occurring usually in men over forty years of age, usually engrafted upon an unstable nervous system, and was complicated by alcoholism and syphilis as well in 85 per cent. of the cases. The early symptoms were of prime importance. Among these were impairment of muscular and cutaneous and joint sensations, disturbances of coordination, vertigo, and gastrointestinal disturbances. Later this train of symptoms was exaggerated until incoordination became marked, the knee-jerk was lost, Argyll-Robertson pupil was noted, and gastric crises and girdle pains were present. Paresis of the physical type was similar to that of the mental type excepting that premonitory symptoms were of the physical rather than of the mental character and remained so during the course of the disease. Apoplexy was a disease of middle life in which physique and heredity played an important part. All overweights past forty years of age, especially if they had an unfavorable family history, should be tabooed. Some of the earlier symptoms were vertigo, fullness in the region of the vertex, nausea, vomiting, tinnitus aurium, speech and gait disturbance, momentary loss of consciousness, and Jacksonian epilepsy. The author concluded his paper with a description of the different varieties of brain tumors and their symptoms, general and local, and stated that they constituted a grave condition at best and that every precaution should be taken to keep these sufferers off the list of policy-holders.

Dr. J. H. Florence of Brownsville, Texas, Medical Director Great Southern Life Insurance Company, said that after all had been said *pro* and *con*, the Medical Director must bear the brunt of the sins of omission and commission of the medical examiners. In these days of high pressure competition and the mad rush for business he must necessarily be the balance wheel in the protection of his company and any errors of judgment should be favorable to the company. From the mortality standpoint this was a subject of paramount importance. The point made that nervous and mental diseases were on the increase could not be successfully contradicted; hence the higher mortality must be sustained. No medical examiner would recommend these cases in the active stages of the disease, but they were absolutely helpless when individuals appeared with incipient or obscure mental and nervous troubles. Some Medical Directors had boastingly asserted that they accepted syphilitics. The fact remained that they

had some of them on their books and had paid claims as a result and more claims were yet to be paid. Unreported syphilis was the *bête noire* of life insurance companies and they were powerless to guard against it in the large majority of the cases. Their Medical Directors could readily detect physical signs such as nodes, discoloration, scars, enlarged glands and locomotor ataxia; yet, on the other hand, the applicant might have had barely enough treatment to prevent or disguise his symptoms; he even might have arteries ready to rupture. It was very essential that the remote and obscure symptoms be recognized. Stress should be laid upon the insidiousness of these pathological conditions; they came as a thief in the night, so silently that they were unnoticed even by those who were in daily contact with them until the explosion came that no one was expecting; then in looking back he could recall that there was something peculiar in the individual's demeanor which was overlooked. The local examiner would regard this a perfect physical risk but he would write you stating that he thought him a "peculiar man." On inspection the report would probably say that he was a first class risk but that he was known in the community in which he lived as "an eccentric." They could not afford to pass lightly over such seemingly unimportant information. Often it was recorded that "applicant was never sick but suffers occasionally from an irritable stomach." One had been dumfounded when a close inquiry was made into the case to find the applicant was bordering on a nervous or mental collapse, yet he might not have consulted a physician. "Loss of memory" had been mentioned as a danger signal; this was very true, but it should not be confused with "lapse of memory" which was so often noted in applicants whose parents had died of tuberculosis. With regard to the percentage of cures in nervous and mental cases, regardless of the favorable reports of cures in some forms of these maladies, they were undesirable lives for insurance before or after recovery. Some of those who were insane lived to a ripe old age, while others succumbed to apoplexy, paresis and other conditions ensuing from syphilis and alcoholism. More emphasis should be placed on heredity in passing upon an applicant, especially in cases of neurotic or alcoholic parentage. Too much stress could not be laid upon the recent statistics of pellagra. In Texas in 1910 there were 117 deaths officially reported from this disease and during the first six months of this year there were 92 reported. Taking the number of unreported cases, likewise those not diagnosed, added to those officially reported, certainly justified attention to the comments contained in the paper. The general public could be educated as to the danger of tuberculosis and other preventable diseases; but as to mental and nervous diseases there seemed little avenue of escape, at least not in the near future. It remained for them to instruct their local medical examiners to put more stress upon heredity, alcoholism and other hitherto seemingly unimportant phases of the physical, mental and nervous conditions of the patients.

Dr. J. H. WRIGHT of Pittsburg Reliance Life Insurance Company, said that within the past three years there had been a reawakening of things neurological and even bills had been passed providing for one month's observation of acute cases in general hospitals. There was no psychopathic clinic at Johns Hopkins Hospital for the study of mental cases. New ideas had developed and the Wassermann reaction had given a newer conception of the psychoneuroses and the movement was going on towards solving questions regarding the insanities and neuroses. The life insurance companies of course would be benefited by this work. There was a movement to take care of this question such as occurred ten years ago when the State began to care for the tuberculous patients. From a life insurance standpoint it was unfortunate that they could not expect their medical examiners to always recognize nervous or mental conditions and this was probably due to the medical schools not giving a full course in these diseases. Again there was a lack of interest in these subjects on the part of the students themselves. Dr. Wright said that he remembered well when he was a student there was very seldom a full attendance at the clinic for neurological or psychological cases. The students who were now being turned out of the medical schools were better equipped and would give better service. The best they could expect at present was to get a frank statement from the applicant regarding any previous mental or nervous trouble. It seemed to him that more investigations should be made as to the condition of the patella and eye reflexes. He had occasion to examine a man who was carrying much insurance, a total of $250,000. He tried his knee jerks and pupilary reflexes, etc., a thing that had never been done before. This insurance was obtained in the City of Pittsburgh; what could one expect in the country towns? These examinations of the reflexes were very important in ruling out tabes dorsalis and paresis, the two diseases of middle life that were so important. A very important question that concerned the work in the office was that regarding the family and previous history and the history of mental trouble. In the insurance blanks where such a history was inquired into, they usually came back filled in with "nervous exhaustion" or "overwork"; under these conditions he thought it necessary to get first-hand information. Dr. Wright's practice was to write to the local medical examiner asking him to get in touch with the physician who cared for the applicant and to learn further regarding him, and not to rely entirely upon the applicant's statements. The family history as ordinarily shown on the medical blanks did not mean anything; it did not impair the risk to any extent. In hospital practice it was common to find that in cases of insanity there was a previous history of it. In St. Francis Hospital it was safe to say that in twenty-five per cent. of the cases admitted with mental troubles there was a previous history of mental disease in the family. But that was not the kind of information that concerned them as life insurance men. Perhaps in the investigations to be published at the end of this year they might have more light on this subject. What cases could be accepted as standard? He believed that any case of neurasthenia occurring in the early twenties could be considered a safe risk. Cases of individuals simply overworked were safe risks. But great care must be taken when such troubles occurred in middle life for they might be the first signal of an oncoming tabes. Always be careful of cases of transient hemiplegia, another danger signal of an oncoming tabes. Oculomotor palsies called for action; in a large proportion of the cases they were due to cerebral syphilis.

Election of Officers.—*Chairman*, Dr. Ambrose Talbot, Medical Director Kansas City Life Insurance Company; *Vice-Chairman*, Dr. H. A. Baker, Medical Director Pittsburgh Life and Trust Company; *Secretary*, Dr. F. L. B. Jenney, Medical Director Federal Life Insurance Company, Chicago, *Board of Managers*, Drs. Ambrose Talbot, F. L. B. Jenney, Jas. H. Stowell, Whitfield Harral, and Herbert M. Woolen. Place of next meeting not yet decided upon.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

AT a stated meeting held October 11 Dr. D. H. BERGEY read a paper entitled "Preventive Medicine: Present Achievements and Future Fields of Activity." He dwelt on the advances that have been made in the control of infectious diseases, emphasizing especially the importance of isolation and disinfection. He pointed out the success that has been attained in the treatment of diphtheria with antitoxin and the prevention by similar means or by the

employment of attenuated cultures or virus or of emulsions of the dead bodies of bacteria of tetanus, typhoid fever, dysentery, cholera, plague, anthrax, and hydrophobia. He showed how chemotherapeutic agents were successful in the prevention and cure of various diseases, as, for example, quinine in malarial fever, trypan red, trypan blue, and atoxyl in trypanosomiasis, and arsenobenzol in syphilis. Further purification of water supplies by filtration and other means have been useful in diminishing the prevalence of typhoid fever and allied diseases and also in improving the general health. The part played by flies and mosquitos in the conveyance of disease also was adverted to. Dr. JOHN A. RODDY presented a communication entitled "Diphtheria Antitoxin and Anaphylaxis." He pointed out that the reaction observed in guinea-pigs following a second injection of blood-serum soon after a primary injection was not as a rule observed in human beings and he presented statistics showing that unpleasant sequels following the prophylactic or curative use of diphtheria antitoxin are rarely observed in the human subject. It is especially after small primary doses that bad effects are to be expected. At the present time it is the general practice to administer large doses of diphtheria antitoxin, from 12,000 to 30,000 units, in the treatment of recognized diphtheria, and smaller doses, from 3,000 to 6,000 units, as a prophylactic in suspicious or exposed cases. In other words there is little or no danger to be feared from the proper curative or prophylactic employment of diphtheria antitoxin. Dr. JOHN J. GILBRIDE read a paper entitled "A Bacteriological Study of Cultures Made from the Thyroid Gland." He reported the results of observations made in 15 cases, 8 of cystic goiter, 6 of exophthalmic goiter, and 1 of carcinoma of the thyroid gland. The findings were negative in all but two cases, and in these it may be concluded that the presence of the microorganisms was accidental.

COLLEGE OF PHYSICIANS OF PHILADELPHIA.

AT a stated meeting held October 4, Dr. ROLAND G. CURTIN read a "Memoir of the late Dr. De Forest Willard." Dr. LEONARD D. FRESCOLN presented a communication entitled "Rabies, with a Report of Cases." He pointed out the antiquity of the disease and emphasized its acceptance as a morbid entity throughout all time. While the disorder had a definite and well-recognized pathology, with characteristic changes in the nervous system, the identity of the causative agent had thus far escaped recognition. Nevertheless the Pasteur method of treatment with graduated inoculation of attenuated virus constituted a reliable therapeutic procedure. It must be employed, however, before convulsive manifestations appear. The best agent for cauterizing the bite-wound was carbolic acid. Dr. Frescoln reported a series of 16 cases, with recovery in those treated by inoculation of attenuated virus. Dr. CHARLES LESTER LEONARD read a paper entitled "Compensation by Displacement of the Thoracic Viscera in Pulmonary Tuberculosis," illustrated by tracings, lantern slides and stereoroentgengrams. He showed how the heart and the great vessels of the chest undergo, not demonstrable by the usual means of physical examination, displacement, in consequence of changes in the lungs and pleura, due to tuberculosis—such as emphysema, pneumothorax, fibrosis, cicatricial contraction, etc. The Committee on Alvarenga Prize announced that the income from the Alvarenga fund, amounting to about $180, was awarded to Dr. Francis D. Patterson for an essay entitled "The Parathyroid Glandules."

Intestinal Obstruction.—R. Morison states that for some years he has taught that the diagnosis of intestinal obstruction is based upon a trinity of signs as follows: (1) spasmodic pain; (2) inability to pass flatus; and (3) evidence of increased peristalsis.—*Edinburgh Medical Journal.*

Medical Items.

Contagious Diseases, Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ended November 4, 1911:

	Cases	Deaths
Tuberculosis Pulmonalis	389	154
Diphtheria	228	19
Measles	113	2
Scarlet Fever	106	3
Smallpox	—	—
Varicella	54	—
Typhoid Fever	94	15
Whooping Cough	46	6
Cerebrospinal Meningitis	8	6
Malarial Fever	—	
Totals	1038	205

Health Reports.—The following cases of and deaths from smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine Hospital Service, during the week ended November 3, 1911:

CHOLERA

Places.	Date.	Cases.	Deaths.
Austria-Hungary: Budapest	Sept. 16-30	3	*1

ONE YEAR'S EXPERIENCE WITH SALVARSAN. BEING A REPORT OF 230 INJECTIONS WITH SPECIAL REFERENCE TO EYE AND EAR COMPLICATIONS.*

BY B. C. CORBUS, M.D.,

CHICAGO, ILL.

PROFESSOR OF GENITOURINARY DISEASES AND SYPHILOLOGY, POST-GRADUATE MEDICAL SCHOOL AND ASSISTANT PROFESSOR OF GENITO-URINARY DISEASES, COLLEGE OF PHYSICIANS AND SURGEONS, MEDICAL DEPARTMENT, UNIVERSITY OF ILLINOIS.

IT is now two years since Professor Ehrlich sent Dr. Konrad Alt some salvarsan for the treatment of syphilitic paralytics, and just one year this month since the Rockefeller Institute received a thousand doses to be distributed in this country for experimental purposes. The questions regarding salvarsan then were the same as now, namely these: (1) Is it an absolute specific for syphilis and does it produce a *therapia sterilisans magna?* (2) Are there any severe organotropic effects?

The time has been sufficiently long for us to draw fairly definite conclusions, but as regards the final solution of the problem we must be content to wait for many years. Already there have been over 60,000 cases treated. The literature is voluminous, mostly from abroad. This is explained by the excellent hospital and clinical facilities in Europe. Those of you who have watched the reports of the application of this remedy must surely agree that salvarsan, if properly applied, is the best aid yet devised to combat syphilis. Here and there in the German, English, and American literature we read adverse criticisms which come from the pens of those who have had little experience, or else, for various reasons, are not willing to concede to salvarsan its merits.

In the literature in this country it is indeed encouraging to read the beginning of the article by Dr. John A. Fordyce,[1] which says: "A more extended experience has not altered my views regarding the value of salvarsan; on the contrary, I am more and more impressed with its extraordinary therapeutic qualities." Also encouraging is the opinion of Faxton Gardner,[2] who says: "Salvarsan has come to stay. Despite all, it is the most powerful agent we have at our disposal against syphilitic manifestations." Still more encouraging is a circular from the War Department,[3] under date of June 3, 1911, authorizing the use of salvarsan in the army, signed by Surgeon-General Towney and approved by the order of the Secretary of War. This, indeed, is the sentiment of all of us that have had any experience at all with the new remedy.

*Read by invitation before the American Academy of Ophthalmology and Otolaryngology, Indianapolis, Ind., September 25, 1911.

In answering the early question, does salvarsan produce a *sterilisatio magna,* we can say that experimentally in rabbits it does, but therapeutically with the dose of 0.6 grams it does not. That it does not produce a *sterilisatio magna* is indeed a blessing, for if it did, it would belittle the infection to such a degree that venereal diseases, instead of becoming less frequent, would increase fifty-fold. As early as the summer of 1910, numerous cartoons and articles appeared in the foreign lay press calling attention to and symbolizing the ease with which syphilis could be cured.

Concerning the second question, we can safely say from the reports of all the cases treated that there are no general organotropic effects in properly selected cases. In an address to the Vienna Society of Physicians, November 18, 1910, Finger[4] expressed some doubts whether the assertion that salvarsan was entirely harmless was justified in view of some of his disagreeable personal experiences in sensory nerves, particularly the optic and auditory nerves. Finger[5] refused to explain the phenomena observed, claiming that it was too early to form a decided opinion, but he called attention to the fact that such phenomena occurred rather frequently and in an unusually early period of lues in patients who are still in the early stages of the disease. He considered it less likely that these cases were independent syphilitic relapses such as would have occurred without salvarsan, because of (1) the possibility of a direct connection of such symptoms with salvarsan; and (2) the possibility of a combined action of salvarsan with lues, in the sense that the remedy created a *locus minoris resistentiæ* in which the lues can be localized.

Schamberg reported in the *Journal of the American Medical Association,* May 20, 1911, all the literature to date in an exhaustive article, citing Finger's cases of optic nerve disturbances and adding reports from Blaschko, Rille, Held, Oppenheim, von Zumbusch, and Fordyce. In the same article he adds Finger's reports in auditory nerve disturbances, also Rille, Kern, Urbantschitsch, Matzenauer, Rusch, Alexander, and others. Werther[6] says that the frequency of such "neuro-relapses" in salvarsan cases is somewhat greater than the proportion to the number of syphilitic cases in general. Risson[7] is astonished that in a small series of patients he observed two cases of optic nerve atrophy. Bettmann[8] insists that these neuro-relapses appear earlier and more frequently than has seemed to be the case before salvarsan. Stern[9] and Waltenhoefer[10] consider their cases toxic. Port[11] thinks that the increased number of such cases makes it little probable that we have to deal simply with relapses, and we must assume a toxic injury to the nervous tissue. Geronne[12] and Gutmann agree with Finger when they say that the number

of such neuro-relapses has increased essentially since salvarsan was introduced, and that the time of the relapses almost without exception has advanced to an early stage. "If in about three hundred cases treated with salvarsan, thirteen neuro-relapses occur, and if these appear mostly four to five months after infection, and six to eight weeks after salvarsan we have evidently something new in the pathology of syphilis which must be brought into causal connection with salvarsan treatment." Nevertheless, these authors accept Ehrlich's view concerning the neuro-relapses. J. Benario[13] was able to prove that the affections in the cerebral nerves observed by the above authors have appeared exactly in the same way under mercury and potassium iodide. He claimed that this settled a part of the question of harm with which salvarsan was charged. At this date, Ehrlich[14] gave the plausible explanation of these phenomena by saying that he considered these forms of the disease as neuro-recurrences of foci, because during the sterilization of the organism some spirochetes had not come under its influence. This in the first place is true of the spirochetes which had settled in the nerves passing through narrow bone channels. These are then principally topographic, anatomical conditions by which are caused the symptoms on the part of the cerebral nerves.

Benario[15] has used all possible means to collect the reports of all the cases of the affections of the cerebral nerves known since the first publication. In this way he has disposed of one hundred and twenty-six single such observations, which occurred in at least 14,000 treated cases. To complete his reports he sent letters to a majority of the authors with a question sheet. From the replies he obtained an abundance of material which permitted a general and convincing exposition of the conditions to be considered. In Benario's[15] question sheet he considered the optic and auditory nerves separately —each in regard to vocation, abuse (such as alcohol or nicotine), through previous ear disease and also whether a previous injection of some other form of arsenic had been given. Numerous other questions were asked, tending to throw sidelights on previous optic or auditory diseases. These reports show that the early secondary stage is particularly predisposed to these neuro-recurrences. He calls attention to the fact that in extragenital primary lesions, especially cephalic chancres, involvement of the nervous system is prone to follow. They occur from a single spirochete focus which had remained from the principal mass at sterilization. This view is further confirmed by the fact that recurrences are found almost exclusively in cases of secondary syphilitics of from two to eight months' standing, where it is well known that a colossal distribution of spirochetes exists. This is substantiated by the following clinical reasons: (1) Long interval between injection and appearance of nervous manifestations. (2) From the nature of the pathological process itself which shows a condition of irritation and inflammation in contrast to atrophic processes observed after other arsenicals. (3) from the fact that the disease appears almost exclusively during a definite period of syphilis. Benario[15] says that it is not fair to charge all recurrences to salvarsan, as we do not realize that the neuro-recurrences occur many times in mercury treatment. Also that we are watching all cases now with greater scrutiny and with a far greater degree of intelligence, knowing well the history of arsenical preparations and especially since Ehrlich warned all observers in regard to the possible neurotropic effect of salvarsan. Benario[15] calls attention to the fact that we must be especially watchful of recurrences in the following classes of cases: (1) Recent secondary states. (2) Extragenital and cephalic chancres, due to immediate proximity to the nervous system. (3) Character of the skin phenomena which are severe from the start. (4) Headaches (invasion into the central nervous system by spirochetes). The above symptoms should serve as a warning for the institution of energetic treatment. He believes that by thus instituting a vigorous treatment with both salvarsan and mercury many neuro-recurrences will be eliminated.

It is true, no doubt, that there are a few limited cases where salvarsan has been productive of harm, but when we consider the enormous number of cases treated and the equally great number of physicians that are administering salvarsan, we wonder that there are not more complications. There is no doubt that the neutral suspension as recommended by Wechselmann has been productive of toxic symptoms, for here the coagulum in some instances has remained in the tissues for months; again careless technique in preparing the alkaline solution both for intramuscular and intravenous administration, both in regard to sterility and excess of sodium hydrate, may be productive of harm. Therefore, before we condemn a substance that has fewer neuro-relapses than there are complications following the administration of choloroform, let us look closely to our technique and have a care that we are perfectly competent to administer the substance.

Indications.—At the present writing, salvarsan is indicated in every case of recent syphilis as the first and most efficient therapeutic agent at our disposal, and in every case where quick action is desired except in diseases of the cardiovascular system, where if it is not possible to obtain a *sterilisatio magna* it is possible to obtain a clinical sterility with one dose, rendering those patients for the time clinically free from their disease-germs. No doubt we could treat the early cases entirely under a salvarsan therapy, but we are not justified in using this exclusive method, especially since salvarsan is a new therapeutic agent and we have such a recognized ally in mercury. From now on salvarsan should be the mainstay of the syphilographer. What its results will be in internal medicine and nervous diseases of syphilitic origin it is not possible to prophesy at present. At best our results cannot be brilliant, as here we have as a rule considerable degeneration of the nervous and cardiovascular system.

In tabes dorsalis, if of only recent duration and accompanied by a positive Wassermann, cessation of further symptoms is possible if the treatment is carried out vigorously by the combined method. What its scope is in ophthalmology, we are not able to tell, as many cases of eye syphilis were in the beginning refused treatment, fearing a neuro-toxic effect of salvarsan. But the administration of salvarsan in syphilitic eye lesions is no longer prohibited. In optic atrophy it is impossible to change the condition by any therapeutic agent once the process has occurred. Care should be used in following up treatment with salvarsan where other arsenicals have been used to any extent, as here a toxic effect caused by some previous application might be laid at the door of salvarsan. Ehrlich's animal experiments indicate that the drug does not exert injurious by-effects upon the optic nerve as do atoxyl

and the related preparations of arsenic. J. Igersheimer[16] considers as the reason for this that salvarsan is not split up in the body into derivatives of phenylarsenic acid, as is the case with atoxyl. Hoppe's[17] investigations showed that salvarsan has only a slight chemical affinity to the nerve tissues, for after three days he could not find any arsenic in the brain, spinal cord, or optic nerve.

Steindorff[18] has recently presented an excellent paper embracing reports on over seven hundred cases on which he bases the following conclusions: He finds that blindness referable exclusively to salvarsan has so far not been definitely determined by anybody. The remedy has a favorable effect in primary and tertiary affections of eyelids and conjunctivæ. In specific dacryocystitis, scleritis, gumma corneæ, and in luetic disease of the orbital bones, salvarsan has rendered good service, at least in the small number of cases observed so far. Parenchymatous keratitis due to acquired lues almost always reacts promptly to salvarsan. In the treatment of parenchymatous keratitis due to congenital syphilis, failures are more frequent than successes. Nevertheless the remedy can shorten the courses of promptly treated cases. In unilateral disease it is only rarely possible to protect the healthy eye. Neuritis, especially if treated early, reacts almost always and rapidly. It is true that the success is sometimes only of short duration and that relapses are frequent. Affections of the choroid and retina are frequently influenced favorably, but sometimes new processes are observed immediately after injection. Very favorable results have been observed in the treatment of specific iritis, especially after the intravenous method. In the treatment of inflammation of the optic nerve and of choked disk, the favorable results of salvarsan predominate. Pareses of the eye muscles are influenced favorably and promptly, but failures are just as frequent. Argyll-Robertson symptom and anisocoria remain unaffected in the majority of cases. In the treatment of syphilitic eye disease then, salvarsan certainly merits attention, especially in combination with mercury and iodine and in cases in which a rapid effect of antisyphilitic treatment is of importance.

Dose.—The dose practically remains the same as at first established, viz., 0.5 gm. for women and 0.6 gm. for men. However, in women I have frequently varied the dose according to the weight, giving sometimes as much as 0.6 gm. and in many, especially in extremely debilitated cases, less than 0.5 gm. Salvarsan can now be obtained in 0.1 gm. ampoules. This is valuable when the substance is to be administered to children, as it insures an exact dose and prevents waste of the product. I am not in favor of fractional doses in adults, except, perhaps, in syphilis of the cardiovascular system, as here the dose must of necessity be small in order not to produce any untoward effects. In primary, secondary, tertiary, and in latent syphilis, I believe the best results are obtained from the largest dose that can be given with safety. As salvarsan acts in two ways, viz., chemotherapeutically and serotherapeutically, we can readily see that if we give a sufficiently large dose of salvarsan and have a large number of spirochetes to combat, our endotoxins will be greater after a large dose than after a smaller one, and in turn will work a greater curative effect in the disease than a smaller dose.

Technique.—The intravenous method has become almost universal on account of its ease of application, the brief inconvenience to the patient, and his rapid recuperation. However, no one method should be used to the exclusion of the others. This is borne out by experience, as in the early cases it is more advantageous to administer the salvarsan intravenously and later to inject it intramuscularly. For the successful carrying out of the intravenous method, some form of a gravity apparatus is preferable, and the more simple of these give the best results.

The method of administering normal saline before and after the salvarsan is recommended only to those who have little experience. Great care should be used to have the saline solution absolutely sterile and prepared fresh immediately before using, as numerous reports[19] have appeared showing a febrile reaction following the injection, which was eliminated entirely by using great care in preparing the salt solution. From the beginning I have not used normal saline solution. The method of preparing the solutions in glass cylinders is vastly superior to the mortar as they are so easily kept sterile. The addition of hot water[20] greatly facilitates the putting of the salt into solution and does not in any way deteriorate its action (Marks). With a two-way cock attachment it is easy to find when one is in the vein. If by chance one has missed the vein the sharp stinging pain and sudden swelling at the point of puncture warns one that he has not been successful. It is an easy matter to stop the solution at once and seek a new point of injection. The resulting extravasated salvarsan, if not too copious, is quickly absorbed without much effect.

In preparing the solution for the alkaline intramuscular method I now use a 2 per cent. solution of sodium hydroxide, giving the injection in the same location as recommended in my previous article. (*Journal of the American Medical Association*, February 25, 1911, page 566.) The method of injecting subcutaneously or intramuscularly in the muscles of the back should be severely condemned. Some of my patients that were injected nine months ago in this way still show large nodular masses. Immediately after the intramuscular injection of the alkaline solution I use hot applications. These are continued for forty-eight hours. The resulting induration and subsequent pain are greatly lessened thereby. All of the alkaline intravenous or intramuscular injections are given in the hospital; except in the severe manifestations the patients are detained only twenty-four hours after intravenous, and forty-eight hours after intramuscular injection.

Oil Suspension Method.—For the large number of clinical patients who cannot afford to go to a hospital, this offers a fair substitute for either the intravenous or the intramuscular injections. The method I am using is as follows: Materials—A large glass mortar and pestle, an all-glass syringe holding 5 c.c., one needle 1½ inches in length, 17-gauge. The needle and syringe are placed in a large test tube with cotton in the bottom of the tube and stoppered with cotton. All the materials are placed in a dry sterilizer and sterilized just before using. Great care should be used to keep all water away from the materials, as the salt on contact with water quickly forms a hard sticky mass that clogs the syringe so that it cannot be injected. Break with a file the ampoule that has been previously sterilized and pour the salt into the mortar. Add about .2 c.c. of 10 per cent. iodipin. This is rubbed in thoroughly until a smooth emulsion is obtained that

is sufficiently liquid to be drawn up into the syringe. This is drawn up and 1 c.c. of iodipin is added, rubbing this up, and this in turn is drawn into the syringe. Then if there is still any salt remaining, a still smaller quantity of iodipin is added and rubbed up. In this way all the salt can be incorporated with the oil; when completed the syringe should hold about 4 c.c. of the finished emulsion. The site of injection (outer quadrant of the buttock) is disinfected by painting with iodine. The needle is thrust in and allowed to remain *in situ* for a minute to see that no vessel is punctured. The connection is made and the emulsion injected, the whole amount being placed in one side. Care should be used to force all of the emulsion out of the needle (by disconnecting and injecting a little air), as any remaining in the fat may produce necrosis. Always cleanse the needle and syringe well with ether (do not use water). The immediate pain after the injection is only slight and there is no shock. How well this emulsion is absorbed will depend upon the thoroughness with which it is triturated. Clinical results with symptoms have been most gratifying in some of my cases. However, on account of its tendency to become encysted, I prefer the other methods.

Prognosis.—With an experience of one year with salvarsan in 124 cases one can begin to draw some definite conclusions. Never in the history of medicine has there been a definite specific that has come into universal use and has, except for a few instances, held its own so well. The more one sees of its remarkable clinical and biological effects the more satisfied one is with having used it. It has come to be the right arm of our therapeutic force, and combined with mercury it works with a swiftness that is truly wonderful. This is especially manifested in primary, secondary, and tertiary lues. The prognosis depends upon our making a prompt diagnosis, for nothing can be so disastrous to a syphilitic as a delayed diagnosis. Here days of procrastination may mean months of treatment. It is so simple to treat the disease at the chancre period, before there is a positive Wassermann present. At this time the first known collection of spirochetes comprises the primary lesion. Comparatively few have escaped into the system. If we bend every effort to make a diagnosis by finding the organism either by the dark field illuminator or india ink stain and apply our treatment vigorously we can limit our disease to a few months instead of years. There is a time-honored idea that it takes many years to cure syphilis, and that we must of necessity spread our treatment out over a long period. As a matter of fact, the duration of the disease is in inverse proportion to the vigor and energy of treatment. The more emphatic the treatment the quicker the cure. I still believe that if we could get a sufficiently large dose of salvarsan and see our primary lesion sufficiently early a *therapia sterilisans magna* would be possible. At first we thought salvarsan was limited to the so-called mercury-fast spirochetes, and those of a severe grade. Yet if it could work wonders here, why pray could it not do equally as well at the incipient stage of the disease. Now the Wassermann is positive in direct proportion to the length of time of the presence of the primary lesion. In other words, it is usually negative when the chancre makes its appearance, and remains so for a short while. As we approach the third week it begins to become positive, and after this it is practically always positive. Here, then, are almost three weeks in which to make a diagnosis. I earnestly beseech everyone to realize the seriousness of the disease and to recognize how simple it is to eradicate the dreaded infection if treatment is instituted early.

Complications.—Since its introduction into general therapeutic use many complications have occurred, far more than have been reported, but on the other hand unquestionably some have been reported which never should have been, as many of the complications are fatalities due to the operator and to a general lack of knowledge of the new therapeutic agent. In the American literature little has appeared in the way of complications and fatalities. In a communication issued May 16 from the Ehrlich[21] institute, eighteen fatal cases are reported following the use of salvarsan. All patients suffered from cardiovascular disease. As a consequence, any patient suffering from aortitis, coronary sclerosis, and endocarditis, should not have the treatment administered. A routine examination of the urine should always be made prior to the injections, as a nephritis may be augmented by the treatment; from the reports of the literature this is a common occurrence. To be sure, if the nephritis is of a syphilitic nature, it may be greatly benefited, as in a case reported by Nador.[22] The great question of whether salvarsan is toxic to the nervous system, especially the nerves of the eye or ear, has been fairly well answered by Benario, of which reference was made in the early part of this article. Undoubtedly the controversy will continue for some time before the subject is settled to the satisfaction of all. In the meantime, we are watching all cases very closely, especially in regard to nervous manifestations both before and after treatment, deriving from this close observation many points that have hitherto gone unnoticed. Here and there in the literature an unfortunate complication or death is reported of some case that seems to have a special idiosyncrasy for the substance. This may follow large doses of any therapeutic agent, and not too much weight should be attached to it.

Abscess and induration are the common complications. These are absolutely avoided by the intravenous injection, and can also be avoided after intramuscular administration, if strict asepsis is carried out, and if the injection is placed in the gluteal region and contains no excess of alkalinity. The method of dissecting out the vein should be condemned, as it is needless and superfluous, tending to complications. A paraphlebitis may occur from a careless and improper technique, but should not prove alarming. Continuing hot applications facilitates rapid absorption. Except for two cases of abscess previously reported, and three cases that developed a paraphlebitis, in 230 injections I have had no unfavorable results. I have repeated the injection as high as five times in one individual; in another four times, and in many cases three times. I have had the eyes examined religiously, both before and after treatment, and up to the present time I have not observed any unfavorable complications.

The Management of Syphilis After the Biological Method.—Soon after the introduction of the Wassermann reaction it was realized that here at last was a tangible guide in the management of syphilitic cases. Attention was called to this fact by Höne,[23] Boas,[24] Purkhauer,[25] Scholtz,[26] Jesionek,[27] and Meirowsky, and by myself[28] in this country in a paper read before the American Medical Associa-

tion in 1910, being a preliminary report on fifty-seven cases treated with mercury from the standpoint of the Wassermann reaction. It is now three years since the observations were begun and the possibility of such a form of treatment is no longer problematical; in fact it is the method recommended by Ehrlich as the only rapid and reliable means of curing syphilis. The efficiency and practicability of the method is recommended by Gavini,[29] Marcus,[30] Letulle,[31] Stumpke,[32] and others, who are the most recent writers upon the subject. Under this form of treatment our aim should be to make a diagnosis as soon as possible and then to begin treatment at once. If we are fortunate enough to begin treatment with a negative Wassermann, so much the better for the patient; if we are so unfortunate as to begin treatment with a positive Wassermann we should bend every effort to get a negative Wassermann as soon as possible and maintain it for at least one year. Many observers think that no matter what the stage of syphilis present one salvarsan injection will be followed by a negative Wassermann. This depends upon two things, namely: (1) the stage at which the disease comes under observation, and (2) the amount of previous mercury treatment. Few observers realize that it takes an extremely energetic form of mercury treatment to change a positive reaction to a negative in a case that has a moderately severe infection. It is true that many recurrences have been reported following the injection of salvarsan. This is not at all surprising when we consider what we are attempting to do. Compare the spirochetes in a patient's body to a room full of flies. Say the room has 500 flies in it and we kill off all but ten. The feeding is good. The room is so large that they are not observed, we think all are destroyed, we close the room and go away for three months. Upon returning we are surprised to find the room as full as it was at the beginning. To have a patient come under treatment and receive one salvarsan injection and to wait for developments is a fatal mistake. If we wish to eradicate his infection we must continue our treatment energetically either with salvarsan or mercury or the two combined, or else we will have a rehabitation of the body by the spirochetes, for a patient that has a positive Wassermann with clinical manifestations of his disease is just as infectious as he was the day he manifested his primary lesion, no matter if it is ten years after the primary infection. The fact is he is in a worse condition, for at this time the organisms, to use Fournier's words, "are anchored in the tissues."

The Combined Treatment.—Fortunately for the syphilitic, salvarsan and mercury work like twin brothers. No matter which one leads or follows, they work with equal efficiency, though salvarsan is, of course, the more powerful agent. We have three recognized ways of giving mercury: rubbings, injections, and internal medication. The method that I have adopted has been rubbings in conjunction with salvarsan. Kromayer, several years ago, devised a mercury mask to be worn at night, basing his idea upon the fact that nurses working in wards where patients were rubbing mercury became salivated. Unfortunately, this mask did not prove practical. By having my patients rub all their mercury into the chest and back and keeping a thin gauze shirt on as long as possible, I believe I get both an inhalation and absorption treatment, as surely some of the mercury is volatilized at the body temperature, and the longer the shirt is worn the nearer it approaches the one-time popular mercury pad and becomes a veritable storehouse for the mercury. I have my patients rub every night; if they desire to take a morning bath I have no objection, but they are instructed not to rub off the mercury. However, twice a week the skin is cleansed with soap and water in a warm bath. In some hands the injection treatment offers the most convenient and best method of carrying out the combined treatment. The pill treatment is only mentioned to be severely condemned. It gives the patient a false sense of security and is nothing short of criminal. From a serological standpoint, basing my views on almost one thousand Wassermann examinations, this form shows the greatest number of relapses.

When Is a Given Patient Well?—At the present time this question is not easily answered. No matter what the stage of the infection, primary, secondary, or tertiary lues, our aim should be: "Get a negative Wassermann in the shortest time possible, but once we get to the negative goal do not stop treatment short of one year; if we do we may have a relapse." In all my cases, as soon as I have attained my goal, I insist upon giving at least one hundred and fifty rubbings and two intravenous injections of salvarsan.

Report of Cases.—All of the following cases have been treated from the standpoint of the Wassermann reaction, regardless of any clinical symptoms. They comprise the following: 1. Chancre. A, before the Wassermann was positive, one case. B, after the Wassermann was positive, four cases. 2. Early secondaries, twenty-three cases. 3. Late secondaries, thirty cases. 4. Latent, forty-four cases. 5. Tertiary, three cases. 6. Syphilis of the nervous system, nineteen cases.

1. A. Before the Wassermann was positive. This case came under observation May 1, 1911, two days after the primary lesion appeared. Wassermann still negative. He received an intravenous injection of 0.6 grams; the local lesion was destroyed. In five days he received an alkaline intramuscular injection of 0.6 grams. During May and June, he rubbed sixty mercurettes, rubbing one in every evening. July 1, he received a third injection of 0.6 grams intravenously and July 17 he received a fourth injection of 0.6 grams intravenously. The treatment in this case I consider to be ideal. It is an intense form of the combined method. He had a maximum amount of treatment for a minimum of infection, with the great advantage of beginning treatment at the earliest possible moment. The patient, based upon my previous Wassermann experience, I considered to be well of his disease forever, but to be absolutely sure I will make the Wassermann examination from time to time during the rest of the year.

1. B. After the Wassermann was positive. In this series there are four cases. The first case was reported February 25, 1911, in the *Journal of the American Medical Association* with picture. November 3, 1910, he received 0.5 grams in alkaline solution intramuscularly. November 28 the Wassermann was negative. December 12, 1910, a second injection of 0.6 gram in alkaline solution intramuscularly was given. He maintained a negative Wassermann test for ten months, the last August 1, 1911. There has been no further treatment of any kind. It was my intention with the other three cases to try a *therapia sterilisans magna*; accordingly each case was given an intravenous injection of 0.6 grams followed in five days by an intramus-

cular injection, alkaline solution method, 0.6 grams. None of these cases ever maintained a negative Wassermann after the first month. All relapsed in four months. Following this, I did not condemn salvarsan, but I did condemn the method; as a consequence all were reinjected and put upon mercury rubbings.

2. Early secondaries. In this series there are twenty-three cases. All have had one or more injections. Fifteen cases have continued under close observation, from five to ten months. Three of these cases are of the original twenty-five cases reported in February. All have had two intramuscular injections after the alkaline solution method, the second injection being given at the sixth or seventh week, on top of a negative Wassermann. These three have remained clinically and biologically negative up to the present time, without any other form of treatment. The remaining twelve have all had three injections, except two cases. Ten have had a negative Wassermann since the second injection. Here the treatment after the second injection has been the combined method, preferably rubbings. The two remaining cases in this series are both instructive and interesting. They were treated in December. Both had lesions (early secondary). They were injected with the alkaline solution intramuscularly, both showed negative blood tests in six and seven weeks. They refused further treatment. In June both patients returned with clinical manifestation and positive Wassermann examination, each having passed from clinical symptoms with positive Wassermann to negative without symptoms and back to positive with symptoms. This shows distinctly how fruitless one injection is in moderately advanced cases.

3. Late secondaries. In this series there are thirty cases. All have been under observation from three to ten months and have had two or more injections except seven cases. The older the infection the more persistent the lesions and correspondingly the more severe the treatment has been; two of the cases in this series have had four injections. One of these cases was not able to obtain a negative result until after the fourth injection; he has had in addition one hundred and fifty rubbings in the last six months. He has since had his fifth injection. Another case in this series with a palmar syphilide of two years' standing with almost continued previous mercury treatment has not been able to clear his clinical symptoms with four injections of salvarsan (two intramuscularly and two intravenously), together with sixty rubbings and twenty injections. The patient has been under observation for six months. Of the remaining twenty cases that continued under my observation, three obtained a negative test after four months with two injections of salvarsan and mercury rubbings. Three obtained a negative after six months with three injections and mercury rubbings. The remaining cases are still positive, all having had two injections combined with mercury rubbings. The reason for this low percentage of negative reactions is attributable to the dilatory attitude of the patients in taking further treatment when all of their lesions were healed and their general nutrition was fairly good. Under this heading I herewith report two cases of syphilis complicating pulmonary tuberculosis, where I administered the first salvarsan injection for Dr. Silvio von Ruck at the Winyah Sanitarium at Asheville, N. C.

H. Pulmonary tuberculosis. Late secondary syphilis, mucous patches. Wassermann positive. April 1, 1911, intramuscular injection of 0.6 gram alkaline solution. Mucous patches healed in one week. After one month, with Wassermann still positive, intravenous injection followed by rubbings for three weeks. One month after the second treatment Wassermann negative. A third injection was given. Wassermann has remained negative. General improvement fair, retarded by digestive disturbances.

L. Pulmonary and laryngeal tuberculosis. Late secondary syphilis. Wassermann positive. Intravenouslar injection of salvarsan April 1, followed by Herxheimer on scalp. One month later Wassermann still positive. Salvarsan intravenously after which Wassermann became negative. There had been a marked general improvement from the first.

4. Latent syphilis. Only manifest by a positive Wassermann. This class comprises the largest number of cases, forty-four. Here occur those infections that have been long forgotten, the so-called skeleton-in-the-closet kind.

Name.	Date of Infection.	Mercury Treatment.	No. of Salvarsan Injections.	Wassermann Test Has Been.
C. E. H.	6 years	Moderately severe	2	Negative for last 5 mos.
J. C.	5 "	Neglected	3	" " " 1 "
D. H. D.	10 "	Neglected	3	" " " 1 "
P. S.	4 "	Severe	1	" " " 3 "

L. M.	7 "	Neglected	2	Positive
M. J.	8 "	Moderately severe	1	"
F. J.	8 "	Moderately severe	1	"

The above table shows clearly that it is possible in a majority of cases to change a positive reaction to a negative, notwithstanding the fact that the infections have persisted a long time in a latent form. Here the possibility of getting a negative test depends upon three things. (1) duration of the infection; (2) amount of previous mercury treatment; and (3) willingness and ability to continue further treatment. Twenty-three of these cases continued under observation and treatment. It will be seen by the accompanying table that it is possible to get a negative reaction in practically all cases. Of the remaining cases four have had two injections each, but have not been seen for five months. The rest have had one injection and have not been heard of since.

5. Tertiary. Unfortunately the cases in this class, after their lesions had healed have not been heard of; all had positive Wassermanns.

6. Nervous syphilis. In this series there are nineteen cases, comprising the following: (1) Cerebrospinal syphilis occurring during the secondary manifestation. One case. (2) Paresis, two cases. (3) Erb's spastic paralysis, one case. (4) Lateral sclerosis, one case. (5) Spinal syphilis, one case. (6) Tabes. *a*. Incipient, three cases. *b*. Moderately advanced with marked ataxia, three cases. *c*. Far advanced, one case. 7. Syphilitic paralysis, three cases. 8. Syphilitic epilepsy, one case. 9. Optic atrophy, two cases.

1. The first case in this series is greatly improved.

He has since gone back to his work, the nature of which I do not know, as he has moved to the Pacific coast. There has been no other form of treatment administered.

2. Paresis. Both cases came under observation fairly early; one case has grown steadily worse. The other case has received a second injection and is working at present. Wassermann still positive.

4. Lateral sclerosis. This case has had two injections. Wasserman still positive. General nutrition is much improved. There has been almost a cessation of neurotic pain.

5. Spinal syphilis. There have been no recent reports; the last report showed improvement.

6. Tabes. *a*. Incipient. Three cases. One case has gained a negative Wassermann, pain has all subsided, the pupils have always reacted, never any ataxia present. The other two cases show marked improvement in nutrition and neurotic pains and an increase in weight. All have had two injections and rubbings, treatment extending over four months. Wassermann still positive. Argyll-Robertson pupil still present. *b*. Moderately advanced. Three cases. Two cases show general nutritive improvement, neurotic pains absent. Each has had two injections and Wassermann still positive. One case with one injection shows no improvement whatever; Wassermann still positive. *c*. Far advanced. One case. No improvement. Wassermann always negative.

7. Syphilitic paralysis. Three cases. All are physicians. Two have had two injections; all showed general nutritional improvement. Wassermann unchanged.

8. Syphilitic epilepsy. One case; no report has been received.

9. Optic atrophy. Two cases. No improvement.

Professional Infection.—In this report are included the cases of twenty-six physicians that have been treated since last October. All had extragenital lesions except two. The reason for this I attributed to the following: (1) carelessness in handling venereal ulcers; (2) the difficulty of differentiating these ulcers without a miscroscopical examination being made. Consequently every physician should hold every suspicious lesion in the light that it is luetic until he positively finds out that it is not specific. In this way both doctor and patient would derive benefit. As a prophylactic measure, we should not forget the application of mercury ointment where there has been an exposure to a specific infection.

CONCLUSIONS.

1. Salvarsan has come to be the right arm of our syphilitic armamentarium.

2. It has not produced any neurotropic effects in properly selected cases.

3. Combined with mercury, it acts with remarkable rapidity in curing syphilis, both clinically and biologically, and therefore is a wonderful advance over the old method of treating this disease.

602 Reliance Building.

THE PRINCIPLES AND APPLICATION OF AUTOGENOUS BACTERIAL VACCINES IN THE TREATMENT OF DISEASES.*

By HENRY A. CRAIG, M.D.,

New Brighton, Staten Island, N. Y.

Pathologist and Bacteriologist, S. R. Smith Infirmary.

The agencies of resistance called into play within the human organism by the entrance of pathogenic bacteria are numerous, but the most important, beyond question, is the action by which the white blood corpuscles take the invading bacteria into their substance and ultimately digest them by means of enzymes, thus destroying them. This property of the leucocytes and of some other cells is called phagocytosis. The doctrine of phagocytosis was established in 1883 by Metchnikoff, who claimed that immunity is a cellular process. This theory found but little acceptance at first, as Behring, Ehrlich, and others at this time, demonstrated a great variety of protective substance in the blood-serum of immune animals, antitoxins, agglutinins, precipitins, bacteriolysins, etc., thus claiming that immunity is a chemical process of the body fluids. Metchnikoff realized that the blood-serum played an important part in the destruction of bacteria, but he thought this was due to the fact that the serum stimulated the leucocytes to increased activity. In 1903 (twenty years later) Wright of England discovered in the blood-serum a substance which acted upon the bacteria, causing them to be more easily destroyed by the phagocytic cells. He called this substance opsonin, from the idea that it prepares the bacteria for ingestion by the phagocytes much as we prepare food by cooking. He proved that opsonins are present in normal serum as well as in the serum of patients suffering from some infectious disease, and demonstrated that the leucocytes are not capable of phagocytosis except in the presence of blood-serum

*Read before The Richmond County Medical Society, New York, September 13, 1911.

containing opsonins. That is, Wright's opsonic theory claims that both the formed elements of the body (the body cells), and the body fluids are equally important in producing immunity. The phagocytes ingest and destroy the invading bacteria, but are able to do this only after the bacteria have been acted upon by the opsonins. Immunity, according to this theory, depends upon phagocytosis and phagocytosis depends upon the opsonins. Obviously then, the degree of immunity depends upon the opsonic content of the blood.

Later it was shown that the opsonins normally present are not the same as those developed in the production of immunity to a certain disease. The latter are absolutely specific, *i. e.*, taphylococcus opsonin, developing as a result of a staphylococcus infection or resulting from the inoculation of a staphylococcus bacterin, prepare only staphylococci for ingestion by the phagocytes. Tubercle opsonins prepare only tubercle bacilli, etc. The opsonins normally present show no such specific action, but act upon all bacteria in much the same way. These two kinds of opsonins are very differently affected by heat. Those normally present are quickly destroyed by a temperature of 60° C. Those developing in the production of immunity are very resistant to this temperature. It can readily be shown by absorption tests that opsonins act upon the bacteria and not by stimulating the phagocytes to increased activity; also, by comparative tests, that the opsonic and bactericidal power of the blood serum in an infection do not run parellel, and therefore are distinct entities. Wright developed the idea that these opsonins are very important in combating certain bacterial infections. He proved that the inoculation of a corresponding bacterial vaccine produced marked changes in the opsonic content of the infected individual and showed that it is possible to measure the opsonic power of the blood-serum of such an individual in relation to the normal—the opsonic index.

The present-day management of bacterial infections, outside of hygiene, sanitation, etc., is summed up in the one word, immunity. Immunity means not only the non-susceptibility of an individual to a given disease and the power to resist infection, but also the mechanism by means of which a cure is effected. Passive immunity is produced by injecting protective substances manufactured in the body of another animal, *e. g.*, diphtheria antitoxin. This is an ideal method of treatment, as the immunity is produced immediately if the antitoxin is administered intravenously and after from six to eighteen hours if given subcutaneously, doing in this time what it takes the body, unaided, a week or more to do. Also it requires no effort on the part of the patient. But the immunity is temporary and the treatment is applicable to only a very few diseases. The diseases caused by bacteria that produce soluble extracellular toxins in their growth are the only ones for which antitoxins can be made. Most bacteria produce intracellular toxins, the toxins being firmly bound up in the bodies of the bacteria, and for these antitoxins cannot be made, although bacteriocidal sera can be produced in the bodies of susceptible animals in some cases and used therapeutically, *e. g.*, antistreptococcus serum. Active immunity is the immunity induced by the production of immune or protective substances within the individual. It can be produced in several ways, but here we are only concerned with Wright's method of producing active immunity by injecting into the patient devitalized bacteria. This is called the vaccine or inoculation therapy.

With Wright's method of treating infectious diseases by small infrequent injections of sterile bacterial vaccines consisting of the organisms causing the disease, we have a new and efficient means of immunization of such far-reaching importance that it promises to revolutionize the treatment of bacterial diseases. Just how and why it acts, we may not be able to explain fully. We know it stimulates the immunizing apparatus into activity and that we are copying nature's methods. In any infection it is by autoinoculation from the site of the disease that the body is stimulated to produce the protective substances necessary for throwing off the infection. Massage, poultices, cupping, Bier's hyperemic treatment, and many other forms of treatment act in this way, *i. e.*, increasing autoinoculation. We noted that passive immunity was immediately produced and required no effort on the part of the patient. Active immunity, on the other hand, requires time and effort on the part of the body. The protective substances have to be manufactured by the body cells. Immunity is gradually produced for a week or ten days, continues for a week or ten days, then gradually declines. Injection of bacterial vaccines stimulates the body cells to produce the protective substances. In case the patient has not sufficient vitality to react, the immunizing substances are not produced and the treatment fails. Therefore the earlier in the disease they are given the better will be the results. They should not be left as a last resort when the patient's vitality is exhausted.

Wright's method of treatment is based upon the following principles. In certain localized infections, the body absorbs but little of the products of bacterial growth or antigens. (An antigen is any substance capable of inducing the production of an antibody.) Therefore, the amount of antigen absorbed being small, the amount of active immunity produced is slight. That is, little or none of the specific opsonins are formed, and those normally present are, to a large extent, used up so that the opsonic index is low and the disease tends to become chronic. In such a case, artificially stimulating the production of the immunizing substances by the inoculation of a proper bacterial vaccine greatly assists the recovery. Or the part infected may be so badly damaged by the severity of the infection that the surrounding tissues are unable to react and form the necessary specific opsonins. In this case, the inoculation of the corresponding bacterial vaccine into a part distant from the site of the infection, where the tissues are uninjured, is followed by an abundant elaboration of the specific opsonins which are delivered to the blood current, are taken to the infected part, and reinforce the infected tissues in their fight against the invading bacteria. Again, the whole system may be overwhelmed by a general bacterial infection, so that no specific opsonins are formed and those normally present are rapidly used up. Hence the opsonic index is very low and the body is helpless to resist the infection. Here it has been proved, in many cases, that the subcutaneous injection of carefully graded doses of the corresponding bacterial vaccine can increase the specific opsonins. For it is the connective tissues and particularly the loose cellular subcutaneous connective tissues that are most active in the production of the antibodies. Bacterial vaccines are never given intravenously, for this would not increase the opsonins, but always into the subcutaneous tissues. It is accepted as a fact that when we inject a vaccine into the subcutaneous tissues, the

local cells that come in contact with the vaccine react and produce the antibodies. These tissues being distant from the focus of the disease and uninjured, are better able to respond.

The opsonins are in the blood serum, and naturally they will act most advantageously when the infection is of such a nature that the blood comes thoroughly in contact with the bacteria. Bacterial vaccines work better in deepseated infections than in superficial infections where the opsonins are less able to get at the bacteria. Thus, in acute urethritis, the gonococci are on the surface of the urethra and are but little affected by the opsonins. In abscesses, liberating the pus by surgical means relieves the tension and allows the inflow of serum containing the opsonins. In tuberculous peritonitis, the abdominal cavity is full of serum from which the opsonins have all been used up. By operation the removal of this serum allows the inflow of fresh serum rich in opsonins and other antibodies, with the rapid cure of the disease. In pleurisy with effusion, which is frequently tuberculous, the same condition prevails, and many of these cases are cured by simple aspiration for the same reason as the above. Wright insists that in carrying out the vaccine treatment one should be guided by the opsonic index. But an immense amount of investigation has revealed the fact that the index cannot be obtained accurately enough to be of much use unless the variation is very great, for it may vary 20 per cent. above or below the average in normal individuals. It varies with the leucocytes used and different strains of bacteria differ in their capacity of being opsonized. Besides the opsonic index is not an accurate measure of the total antibodies in the blood serum. From extensive experience the proper average dose and interval between doses is being worked out. With the aid of a general rule clinical symptoms are quite a sufficient guide for carrying on the treatment without the opsonic index, according to many authorities.

Bacterial vaccines consist of a suspension of bacteria in normal salt solution, killed by heat (55° to 60° C. for an hour), carbolic acid one-half per cent. or lysol one-quarter of one per cent. being added as a preservative and standardized by enumeration and dilution, so that a cubic centimeter contains a certain definite number of bacteria, varying according to the dose of the different bacteria. Autogenous vaccines are prepared from the bacteria obtained from the patient under treatment. Stock vaccines are made from bacteria morphologically similar but from other source than the patient treated.

The question of autogenous versus stock vaccines has been given great consideration. That the use of an autogenous vaccine is scientifically correct must be admitted, providing, as it does, a vaccine of exactly the same kind of bacteria as those causing the infection. The best practice is to give a stock vaccine for the first dose and, if possible, to continue the treatment with an autogenous vaccine. Sometimes it is impossible, from the nature of the infection, to obtain a culture from the patient, *e. g.*, appendicitis before operation. Moreover, the gonococci, tubercle baccili, and typhoid bacilli from different cases seem much alike, so that it is customary not to attempt to get an autogenous vaccine of these bacteria, especially as they are difficult to isolate from the patient, require special media, time, etc. But in all other bacterial infections, to get the best results, the treatment should be carried out by an autogenous vaccine whenever possible. There are many strains of each great group of bacteria. Some one has estimated that there are probably as many as seventy different strains of streptococci and nearly as many different strains of the colon group, etc. So in using a stock vaccine, it can readily be seen what a small chance there is of getting the same strain of bacteria as the one causing the infection, even if the right group is diagnosed and a morphologically similar vaccine is administered. In some of the stock vaccines on the market, attempts to obviate this difficulty are made by preparing the vaccines of a number of different strains of the bacteria; these are polyvalent vaccines. Naturally, an autogenous vaccine must contain a strain of bacteria exactly similar to that causing the infection, providing the bacteria at fault grow in the media used.

Many infections are mixed, and one is unable to determine which is the principal offending organism in order to administer a corresponding stock vaccine. But an autogenous vaccine can be prepared containing all the varieties of bacteria present: a mixed vaccine. Moreover, in chronic infections, the bacterial flora may change, the original bacteria dying out and others taking their place. With an autogenous vaccine, one can keep it up to date by making a new one.

During the past three years, bacterial vaccines have been used in thousands of cases, and there is getting a very extensive literature upon the subject. All writers agree that while they have seen cases in which no results were obtained, the cases not being suitable for vaccine treatment, still they have never seen a case in which any bad results were obtained from the use of vaccines. Naturally, there being no foreign serum in a bacterial vaccine, there can be no cases of serum sickness following such as often follow the administration of the various sera.

This paper is based upon eighty-five cases treated by the writer for various forms of bacterial infection, using bacterial vaccines, in most cases autogenous. This has necessitated the administration of several hundred doses of vaccine, without any harm resulting. Sometimes there is local redness and soreness at the site of inoculation for a day or two. In looking over some of the literature the writer found about three thousand cases reported quite in detail and as many more, less in detail. These cover sixty-seven different conditions treated by bacterial vaccines, indicating the tremendous field that vaccine therapy covers.

The best results from vaccine treatment have been obtained in cases of infections due to the pyogenic cocci. In these conditions bacterial vaccines have established their right to first place in treatment, after surgical measures. Fifty of the present series were of such a nature, four of them in diabetics, including cases of cellulitis, carbuncles, furunculosis, septicemia, erysipelas, etc. Twenty of the cases were due to the streptococcus, pure or mixed with other pyogenic cocci, especially the *Staphylococcus pyogenes aureus*. Every case of cellulitis cleared up rapidly no matter how severe. Some of the patients were saved from the necessity of having crippling operations performed upon their hands, etc., in cases of extensive cellulitis of the hands, arms, etc. One case in particular, a man seventy-three years old, received an injury over the knuckle of his right index finger by striking another man in the mouth, a tooth causing the injury. A very severe streptococcus infection resulted with gangrene of the finger, necessitating amputation. The infection, however, spread into the hand, involving the ten-

dons, and above the wrist into the forearm. The patient was septic and in bad condition. Rather than mutilate his only hand (the other had been lost years before), an autogenous streptococcus vaccine was administered several times, which controlled the infection without an incision being made into the hand. He had a perfect result except for the loss of the index finger. Another case is just convalescing from almost an identical condition, excepting that it was not as severe.

A man who had been subjected to amputation of toe, foot, leg, and finally at mid-thigh in an unsuccessful attempt to get above a mixed streptococcus and gas bacillus infection, was finally saved by an autogenous vaccine. Another severe case of streptococcus infection of foot and leg, following operation for osteomyelitis of metatarsal bones of foot was readily controlled by an autogenous vaccine. The infection spread rapidly after the operation, and the patient had a marked fever until it was controlled by the vaccine. He received four doses of the vaccine and obtained a splendid result.

One of the most remarkable cases in the series was a young girl suffering from a very severe streptococcus angina in the course of scarlet fever. When first seen by the writer she had a rectal temperature of nearly 107°, and a pulse of 160, and was profoundly septic. Her throat was greatly swollen and covered with membrane. It looked like a sloughing mass. The cervical lymphnodes were enormously swollen. She was unable to swallow and barely able to breathe. The cultures showed pure streptococcus, no diphtheria bacilli. She was immediately given a streptococcus vaccine made a few days before from a case of acute otitis media following scarlet fever, and the treatment carried on subsequently by an autogenous vaccine. The result was most remarkable. The throat cleared up rapidly and two days later she was asking for something to eat. She received but two doses of autogenous vaccine. A few days later she was desquamating. The swollen lymph nodes in the neck rapidly subsided without suppuration and no infection of the ears followed.

Three cases of erysipelas cleared up in a few days. Cases of furunculosis and carbuncles responded nicely. Several cases of carbuncles in diabetics cleared up in a few days while they gave a history of having had similar carbuncles lasting for weeks. One case in particular, an old lady of seventy, very obese, urine loaded with sugar, started with an ordinary carbuncle of the neck, which was opened in the usual way. The infection spread, however, producing a diffuse purulent infiltration of the subcutaneous tissues extending from the seventh cervical vertebra all the way up to her eyebrows. The scalp was a great boggy mass, with pus exuding in many places. She was treated with an autogenous staphylococcus vaccine and recovered without any incisions being made. The effect of the vaccine was very marked. Another case, a woman with a large number of deep furuncles in her right axilla. The condition had lasted two weeks and was very painful. The patient was worn out by the pain and loss of sleep, her axilla was full of deeply indurated masses, some of them full of pus. She was cured in five days by an autogenous staphylococcus vaccine without any incisions being made into the axilla.

Several cases of empyema were apparently shortened. One case had a pneumococcus empyema following lobar pneumonia, which was treated successfully by aspiration and pneumococcus vaccine. Later it recurred with the colon bacillus as the infecting organism, and was sucessfully treated by drainage and autogenous colon vaccine. The patient finally died of a ruptured aneurysm of the aorta.

A case of colon bacillus septicemia following death of the fetus and a right pyelitis was cured by an autogenous vaccine made from the organisms found in the blood. The prognosis seemed to be very unfavorable at the beginning. In another case of sepsis following abortion the blood cultures were negative, but streptococci were found in cultures taken from the cervix. The patient was treated in the usual way plus the administration of an autogenous streptococcus vaccine and made a very satisfactory recovery. Another case of staphylococcus septicemia in a man following osteomyelitis of the tibia, developed acute endocarditis. An autogenous staphylococcus vaccine brought the temperature down from 106 to normal, but he died very suddenly from embolism of a cerebral artery.

Ischiorectal abscesses were apparently shortened in their course. Even when occurring in patients dying of tuberculosis, they improved. A man, sixty-five years old, came into the hospital at the end of a prolonged spree. He was on the verge of delirium tremens and had a very severe appendicitis. He was in such a bad condition that it was considered hopeless to operate and the last rites of his church were administered. He was given a vaccine made from the interior of an appendix removed the day before from a very severe case of perforative appendicitis, the vaccine being ready for the patient in case he needed it. It consisted of a mixture of streptococci and colon bacilli. The patient made a remarkable recovery, was out of bed in a week and left the hospital four days later. A case of acute otitis media and beginning mastoiditis was treated by an autogenous streptococcus vaccine which soon controlled the infection. The patient had a high fever, but on account of his age (seventy years) and very bad general condition, it was not considered advisable to operate. He made a very satisfactory convalescence. Another man, seventy-six years of age, had been afflicted with lupus for years which had resisted all kinds of treatment. His face was terribly scarred and covered with crusts with suppuration going on underneath. Unable to open his eyes on account of the contracting scars. He was so repulsive looking that his fellow-patients objected to having him around, so that his condition was pitiful indeed. He was treated with an autogenous staphylococcus vaccine for three months, at the end of which time all the ulcers, etc., on his face had healed with the exception of one on the point of his chin, which had become epitheliomatous. He subsequently died of carcinoma of the sigmoid and liver. He had had two different kinds of cancer at the same time.

The treatment is very efficacious in assisting closure of sinuses following operations. A woman operated upon four months before for appendicitis had a persisting sinus that resisted all efforts to make it close. It was treated by an autogenous vaccine, three doses of which caused the sinus to close. Another case, a man, had a similar condition following operation for appendicitis twelve weeks before. Four doses of an autogenous vaccine closed his sinus.

In looking over some of the literature, the writer found 155 cases of local infections reported (cellulitis, abscesses, fistulas, sinuses, etc.). Eighty-one were cured, 55 improved, 19 not benefited. Of 61

cases of postoperative infections 50 were cured, 7 improved, 4 not benefited.

	Cases	Cured	Improved	Not Benefited
Pyemia	14	11	1	2
Septicemia	186	155	10	21
Puerperal septicemia	155	141	4	10

Leary reports forty-seven cases of puerperal septicemia with but four deaths, and of these two were moribund when treatment was begun. Hartwell reports eighteen cases without a death. Van Cott reports eighteen cases with but one death, the last case being moribund when treatment was begun. Martyn's case received three doses of antistreptococcus serum without the slightest effect before vaccine treatment was adopted, which produced rapid recovery. Waters and Eaton report fifty cases with "almost perfect" results, many of which cases had been pronounced hopeless.

	Cases	Cured	Improved	
Pyorrhea alveolaris	76	46	25	5 not helped
Acute ulcerative endocarditis	29	13	8	8 not benefited
Empyema	28	16	4	8 " "
Pyelitis	14	8	3	3 " "
Cystitis	62	42	13	7 " "
Pyelonephrosis	2	1	1	
Furunculosis	156	141	12	3 " "
Carbuncles	24	23	1	
Acne	139	74	48	9 " "
Sycosis	28	13	11	4 " "
Eczema	7	3	4	
Impetigo	2	2		
Otitis media	38	21	13	4 "
Mastoiditis	8	5	2	1 "
Peritonitis	4	3	..	1 " "
Cholecystitis	3	all cured		
Ulcerative colitis	3	cured by	colon va	ccine
Erysipelas	106	101	1	4 not benefited.

The duration of treatment cut into half. Van Cott reports thirty-five cases of erysipelas: two died; one was moribund when treatment was begun, the other was a baby of six months, who died of exhaustion. The average duration of the disease was 4.3 days.

From the laboratory of the Massachusetts General Hospital last year the results of ninety-seven cases treated by vaccines are given. Twenty-four cases of general infection, eighteen of which were puerperal; all recovered. Twenty-two cases of septic abdominal wounds, due to the colon bacillus, staphylococcus and streptococcus; all recovered. In some of the cases where the wounds had remained for some time, improvement seemed to immediately follow the administration of the vaccine. Forty-one cases of local sepsis all recovered, twenty-five of them due to the streptococcus. A number of cases of pneumonia treated by the writer using pneumococcus vaccine have been reported.* Pneumonia is one of the diseases in which the applicability of vaccine treatment is debatable. Those who claim that bacterial vaccines are applicable for local conditions only advise against using it in pneumonia. It is possible to isolate the pneumococcus from the blood in from 50 to 90 per cent. of all cases of pneumonia; therefore this is really a septicemia. All the cases of pneumonia treated by the writer were in an institution for old men (Sailors' Snug Harbor), among a very unfavorable class of patients. Nearly all the inmates are over sixty, 50 per cent. are over seventy, and 11 per cent. over eighty years of age. One patient of ninety recovered. Nearly all have chronic nephritis, bad hearts and arteries; many are alcoholic, etc. The previous mortality for five years had been 66 per cent., as pneumonia always has a high mortality among such patients. The mortality was reduced to one-third what it had been by the use of autogenous pneumococcus vaccine. For over a year, ten consecutive cases, there was not a death in the institution from pneumonia. Then a case complicated by purulent pericarditis, another with acute uremia, acute dilatation of the heart and a very severe case of double pneumonia, who died from the intensity of the infection, spoiled the record and brought the mortality of the series of twenty cases to 20 per cent. Still the contrast with the previous treatment was marked. Only one case died directly from the pneumonia. From the literature 149 other cases were found reported with an average mortality of 13 per cent. Musser and Norris in Osler's "Modern Medicine," in an analysis of 43,455 cases, found the average mortality of pneumonia to be 21 per cent. So that even a reduction of the mortality to 13 per cent. is worth while.

*Medical Record, February 12 and October 15, 1910.

The first use made of bacterial vaccines in typhoid was a prophylactic measure, as advocated by Wright, to make individuals non-susceptible to the disease. A number of governments, especially the United States and England, have taken it up and inoculated many of their soldiers, so that thousands of cases have been so treated. Two or three injections are usually given: first, five hundred million, ten days later one billion, and ten days later another dose of a billion. The result is to greatly diminish the number of cases of typhoid and to diminish the mortality in those that do get it. Among 11,171 men immunized against typhoid, reported by the Surgeon General of the United States army, there were but three cases of the disease and no deaths. England reports 6000 soldiers immunized against typhoid and 6000 not immunized, living in the same environment. There was but one-seventh the number of cases and one-eleventh the number of deaths among the immunized as compared with those not immunized. Leishman of the British colonial army reports 39 deaths per 10,000 soldiers, not protected by inoculation, and but 3.6 deaths per 10,000 immunized soldiers. In the Spanish-American war, one out of every six American soldiers contracted typhoid; in those regiments left in the country, one out of every five. There were 20,738 cases, with 1580 deaths, all in three and a half months. Recently on the Mexican border, 18,000 soldiers have been mobilized for two months and all immunized against typhoid. There was but one case, in a teamster who was not protected by inoculation, and one mild case in a recruit, both incurred before reaching the camp. The treatment of typhoid by bacterial vaccines has given very good results. Callison of the New York Post Graduate Hospital has collected 323 cases so treated, with but seventeen deaths, or 5 per cent. He uses stock vaccines entirely and concludes that the vaccine prevents relapses and lessens complications. Typhoid vaccines may also prove of great value in carrier cases, judging from the small number of cases reported.

A number of writers report excellent results from the use of gonococcus vaccine. As stated before, superficial infections, where the blood does not come into intimate contact with the invading bacteria, do not do as well as deeper infections. Thus, acute and chronic urethritis yield less satisfactory results than in the case of metastatic infections. Especially good have the results been in cases of gonorrheal arthritis.

In the majority of cases, the symptoms are ameliorated and the joint is restored to its former function. Of 246 cases found reported in the literature, 126 were cured, 91 improved, and 29 not benefited In such obstinate infections as gonorrheal vulvovaginitis in children, the gonococcus vaccine has proved to be of great value. Of 211 cases reported, 100 were cured, 104 improved, 7 not benefited. Hamilton reports a contrast of the old method of treatment with the vaccine treatment. By the former, 60 per cent. were cured; by the latter, 90 per cent. were cured. The average length of time for the treatment by the old methods was 10.1 months; by the vaccine treatment, 1.7 months. Gonococcus vaccine has also been used in urethritis, epididymitis, prostatitis, salpingitis, conjunctivitis, and iritis with encouraging results, though the number of cases is small.

When Koch first announced the preparation of his tuberculin, it was enthusiastically taken up as a specific for tuberculosis. As the result of zeal and inexperience, many times too large doses were given, severe reactions occurred, and much harm was done. With this in remembrance, there is a deep-seated prejudice against treating tuberculosis by the inoculation method. But it is gradually coming to its own. In certain German sanatoria, notably that under Hammer at Heidelberg, this treatment is used in practically every case. Not only in incipient cases but even in the advanced cases, where it will at least alleviate the symptoms and prolong life. It is in cases of incipient tuberculosis and so-called surgical tuberculosis of bones, joints, etc., that the treatment is of the most value. Raw of Liverpool reports 1600 cases of surgical tuberculosis and says the results have been successful beyond all expectations. Trudeau, who has used it at the Adirondack Cottage Sanatorium in many hundreds of cases, says it stimulates the defensive resources of the system, is a valuable aid in the treatment of the disease, and the lives of thousands of cases of incipient tuberculosis and even of advanced cases when chronic in type as well as cases of surgical tuberculosis, may, in many instances, be saved or prolonged by this treatment without any change in their environment. It is possible for but 10 per cent. of all cases of tuberculosis to go to a sanatorium. The other 90 per cent. are obliged to stay at home, and should have the advantage of the specific treatment in their homes, as they can be so treated with little interference with their business, according to a number of authorities. There are 10,000 deaths from pulmonary tuberculosis in New York every year and 22,000 new cases reported. Most of these are wage earners and cannot leave home for sanatorium treatment, even if there were enough sanatoria to accommodate such a number. The Massachusetts General Hospital, Boston Consumption Hospital, and Good Samaritan Day Camp of Boston are all treating patients in their own homes in this way, with great benefit. Hawes, from the above institutions, reports 80 cases of pulmonary tuberculosis, 29 incipient, 20 moderately and 31 far advanced. Fifty-four per cent. were cured or arrested, 11 per cent. improved, 11 per cent. unimproved, and 24 per cent. dead—results comparing favorably with the best sanatorium treatment. In this class of patients, without the treatment, practically all would have gone on to a fatal issue. Altogether he reports 143 cases of various forms of tuberculosis; 14 per cent. have died, 11 per cent. have shown no improvement, and 75 per cent. are cured or improved. In no instance was there any harm done.

Denys recently reported 470 patients in all stages of phthisis attending his clinic. Seventy-one per cent. have recovered or improved greatly. He claims that these remarkable results were due to the inoculation treatment, as it was impossible to make any radical change in their mode of living. Trudeau, from the Adirondack Cottage Sanatorium, reports that of the moderately advanced cases treated in the sanatorium for ninety days or more, 6 per cent. are apparently cured by the routine method, while if given tubercle vaccine in addition, 27 per cent. are apparently cured (four and a half times as many). About an equal number are arrested by the two methods. By the routine treatment, 43 per cent. are unimproved, while when given the specific treatment in addition, but 18 per cent. are unimproved. For the incipient cases there is a slight advantage for those receiving the vaccine, but nearly all do well in this stage by either method of treatment. Still relapses are much less frequent among those receiving the vaccine. Pottenger of the sanatorium at Monrovia, California, has used it in many hundreds of cases, and observes that a great percentage of favorable results are obtained, they do not develop as many complications and extensions of the disease, improve faster, thus saving time, and do not suffer relapses nearly as often. He writes that tuberculous laryngitis yields readily, fistula in ano, tuberculous lymph nodes, tuberculous otitis media, and tuberculosis of the genitourinary tract have almost universally been improved and a fair percentage of them cured by tubercle vaccines.

The writer has several cases under treatment by this method, but it is too early to publish results. One case, however, is very interesting. A man of forty, with a very marked tuberculous family history, and who no doubt had had the disease himself a year or more, when first seen by the writer, was having very severe pulmonary hemorrhages and was coughing up great quantities of blood for several days. He had a high temperature, rapid pulse, great loss of flesh and strength, and the prognosis appeared to be hopeless. His lesion was in the upper lobe of the right lung. It was impossible for him to go away to a more favorable climate. Since treatment by tubercle vaccine was begun by the writer, in less than two months, he has gained twenty-eight pounds and has gone back to work, feeling greatly improved. Another case, a woman of twenty-five, whose father and sister have recently died of pulmonary tuberculosis, has marked involvement of the upper lobes of both lungs with beginning cavity formation in the left and sputum loaded with tubercle bacilli. She has been under treatment but a short time, but has already shown marked improvement—less cough, a gain in weight and strength, much less fever, etc.

In tuberculosis of the lymph nodes, this treatment is especially applicable, giving better results than any other form of treatment, especially after a partial operation has been done. The writer has found the following cases reported in the literature of tubercle vaccine:

	Cases	Cured	Improved	Not Benefited
Tuberculous adenitis	162	81	52	19
Renal tuberculosis	24	10	12	2
Tuberculous peritonitis	6	all cured	or impm	ved but one
Tuberculous Cystitis	21	5	13	3
Tuberculous laryngitis	6	4		2
Tuberculous epididymitis	12	6	5	1
Lupus	50	11	31	8
Tuberculosis of bones and joints	105	15	65	24

These latter are more resistant to the specific treatment, as there is so often dead bone present. Thus, of 386 cases of various tuberculous conditions reported by a number of observers, 80 per cent. were cured or improved, which certainly proves the value of the treatment.

In conclusion, although not claiming that the use of bacterial vaccines is a cureall, still, for suitable cases, it makes a very useful addition to our armamentarium in the treatment of bacterial infections, approaching much nearer being a specific than any drugs we have for the same cases. It does not interfere with the methods of treatment at present in use and can but add to the effectiveness of the same, being apparently productive only of good. It would be an excellent procedure in every operation upon an infected case, such as appendicitis, pyosalpinx, cholecystitis, to take cultures at the time of the operation. Then an autogenous vaccine could be prepared in case the subsequent course of the patient necessitates its use, or even given to the patient, in cases where trouble seems imminent, in the hope of so increasing his powers of resistance as to make a general infection improbable. The use of bacterial vaccines is not intended to take the place of surgical measures, but it is often a very useful adjunct to surgical measures. The reports of the vaccine treatment in recent medical literature seem almost invariably favorable. Some have obtained excellent results with stock vaccines, and it sems reasonable to expect much better results from the use of autogenous vaccines. The treatment certainly has the promise of a brilliant future, and doubtless will become our mainstay in the treatment of all bacterial infections. Perhaps even some allied form of treatment will conquer cancer, a disease which as yet baffles control.

42 Franklin Avenue.

TYPHOID FEVER WITH RELAPSE AND MULTIPLE COMPLICATIONS.*

By AUGUSTUS A. ESHNER, M.D.,

PHILADELPHIA, PA.

Incalculable benefit, particularly in the direction of morbidity and mortality, has resulted from the evolution of bacteriology and animal parasitology, and the coincident knowledge of the causative factors of disease, their vital activities, and their manner of dissemination. In the absence of this knowledge, which would have been beyond attainment without enlightened animal experimentation, malarial fever and yellow fever would still be the scourges of tropical and semitropical countries, destroying their thousands annually and rendering impossible the regeneration of Cuba, and the construction of the Panama Canal. For the same reason we have lost fear of an invasion of our shores by such diseases as cholera and plague. Further, we have learned to manage rationally the entire group of infectious diseases and to treat a number of them with specific remedies. Diphtheria and epidemic meningitis no longer engender a feeling of hopeless and impotent dread, and even tetanus can be approached with prospect of cure.

Typhoid fever is no longer looked upon as a pestilential visitation, tamely and complacently to be submitted to, but it has been definitely demonstrated to belong to the group of communicable diseases, and its spread can, in most instances, be traced to neglect of some hygienic observance. From having been one of the commonest diseases of civilized life typhoid fever has, in recent years, become in many communities one of the rarest. A large part of this good result is to be attributed to purification of the water supply, the medium through which infection is most commonly conveyed. In the city of Philadelphia, for example, where formerly each week saw recorded many cases of typhoid fever, with numerous deaths, since the installation and operation of an adequate filtration system the number of both has been enormously diminished, so that for weeks at a time not a case or a death is reported. Typhoid fever may at the present time be placed among the disappearing diseases, and the time is probably not remote when the individual practitioner will have as little experience of this disease as he has of typhus fever and of smallpox.

Typhoid fever is thus the token of hygienic transgression. It thrives where dissemination of typhoid bacilli is permitted, whether by water or by food or by direct transference, and it disappears in proportion as such dissemination is prevented. The disease could be eradicated if the excreta of infected persons and of bacilli-carriers, and the bodies of its victims in fatal cases, were destroyed. Disinfection of stools and of urine and cremation are the logical steps in this direction. Water used for drinking and for domestic and collateral purposes is the principal medium for the conveyance of the causative germ. Boiling and filtration are the most successful correctives in this connection. Protective inoculation with the dead bodies of typhoid bacilli has proved a highly useful prophylactic measure.

The symptomatology of typhoid fever is protean and it has been quite fully written. Its etiology is securely established, its lesions well recognized, and its pathology clearly understood, while its complications are multifarious and may involve any of the structures of the body. An individual case is entitled to record only if it present extraordinary features. The concurrence of nephritis, intestinal hemorrhage, parotitis, neuritis, and hyperpyrexia as complications in the course of an attack of typhoid fever, with persistence of typhoid bacilli in the blood to the twelfth week of the disease, would seem to meet this requirement.

Case.—The patient was a woman, thirty years old, who, when seen on August 26, 1910, had been feeling badly for three weeks and had been in bed for two weeks. She gave a history of having been seized with chilliness, followed by headache, abdominal pain, pain in the chest and elsewhere, with slight nosebleed. The appetite was poor, the tongue coated, though red at the tip, the bowels loose, the stools watery, yellowish, offensive. There was slight cough with scanty, not rusty, expectoration. The temperature range had been for a week between 101° and 104.5°, the pulse 84. A few rose spots were distinguishable on the abdomen, but the spleen was not palpable. The heart and lungs presented no physical abnormality.

When the patient was admitted to the Polyclinic Hospital on the date mentioned the temperature was 102.6°, the pulse 104, the respiration 32. The urine had a specific gravity of 1018 and it contained albumin and granular tube-casts, but no sugar. A blood-serum test made two days later yielded a negative agglutination reaction with typhoid bacilli. The bowels

*Read before the Medical Society of the State of Pennsylvania, at Harrisburg, September 27, 1911.

continued loose and on August 30 a small hemorrhage from the bowel was noted, with an accompanying moderate decline in temperature. On the following days also two stools contained small amounts of dark blood. Likewise on September 2 old blood-clots were detected in two stools. On this day the patient appeared somewhat irrational and she complained of hearing badly. On the next day the right parotid gland was found painful and swollen, and the temperature had risen slightly. By September 5 the temperature had fallen to the 99° level and on the 6th a positive agglutination reaction was obtained. On the latter date the left parotid gland also was painful and swollen, though in lesser degree than its fellow. During the following week the temperature fluctuated between 99° and 102.4°, reaching normal on September 14. Examination of the urine on September 7 disclosed again the presence of albumin and granular tube-casts. On the 9th the urine still contained albumin, but the temperature continued at the normal level until September 18, when it began to rise again, reaching 102.6° on the following day. From this time on it pursued an irregularly febrile course till October 29, when it reached and finally remained at the normal level. During this period it rose to 105° on October 9; to 106.2° (with a chill) on October 18; to 106.6° (with a chill) on October 22. On September 19 the swelling of the right parotid gland increased greatly, as did also the tenderness, the tumefaction extending as far as the tissues about the right eye. The gland felt hard and the overlying skin was discolored. The presence of pus being suspected an incision was made, but no discharge followed. Attempts at culture from the parotid gland yielded negative results. The urine still contained a trace of albumin but no casts.

On September 24 the patient complained of pain over the gall-bladder and in the lower extremities. A positive agglutination reaction was obtained with the blood-serum on September 26, and the leucocytes numbered 8,500. On October 5 there was complaint of severe pain in both lower extremities, particularly in the right popliteal space. The urine was now free from both albumin and casts, although a trace of albumin was detected again on October 15 and October 26. Some edema about the left ankle was noted on October 15, but this was attributed by the patient to an accidental injury. Pain and tenderness persisted in the left popliteal space, the former being increased by extension of the leg. On October 15 the number of leucocytes was 9,000, on the 19th 8,300. Malarial plasmodia could not be detected in the circulating blood. A cutaneous tuberculin test also yielded negative results. A blood-culture on October 29 yielded a pure growth of typhoid bacilli. The patient was dismissed, well, on November 11, after an illness lasting thirteen weeks.

Nephritis.—Albuminuria is a common manifestation of febrile and infectious diseases generally. In the course of typhoid fever it often appears early, generally disappearing with the remission of the symptoms of the disease. Occurring as part of an acute nephritis it usually develops in the second week, persisting for a variable period of time. Rarely acute nephritis occurs as a sequel of typhoid fever. At times it dominates the onset of the disease, constituting so-called nephrotyphoid. Of course, typhoid fever may develop in a person previously nephritic. In a series of 1,500 cases observed in the wards of the Johns Hopkins Hospital acute nephritis was noted clinically in ten cases, and it was found in eight among 105 fatal cases that came to autopsy (McCrae, "Modern Medicine," vol. II, 1907). According to Curschmann the incidence is 1 per cent.

Intestinal hemorrhage occurred in 118 of the 1,500 Johns Hopkins Hospital cases, 7.8 per cent., with 12 deaths, 10.2 per cent; and in 1,641 among 23,271 collected cases, 7 per cent. It was less common early in the disease (first week), and is then due to oozing from the hyperemic bowel. Later it is due to erosion of a blood-vessel in the course of the ulcerative process. It is most common between the second and fourth weeks and relatively rare during relapses. It may take place but once or be repeated.

Parotitis was observed in 14 of the 1,500 Hopkins cases, 0.9 per cent, and in 93 of 12,173 collected cases, 0.76 per cent. It results from infection conveyed either along the duct of Stenson or through the blood. It usually occurs during the third week or later, sometimes during convalescence. One gland alone may be attacked or both may suffer in succession. The swelling generally persists about a week, although it may continue a longer time. Necrosis and sloughing of the parotid gland may result. About 30 per cent. of the cases complicated by parotitis terminate fatally.

Hyperpyrexia.—Dreschfeld in Allbutt and Rolleston's "System of Medicine," Vol. 1, 1905, states that the temperature may be "very high" on the second day of an attack of typhoid fever, particularly if pneumonia supervene. It may reach 105° or 106° toward the end of the second week and recovery ensue, especially in young subjecets. Occasionally the temperature reaches 109° or 110°, generally in the third week, and a fatal issue is the rule. Among the 1,500 Hopkins cases the temperature reached 104° or above in 1,118; between 104° and 105° in 643; between 105° and 106° in 411; between 106° and 107° in 58; and 107° or above in 6.

Neuritis is not a common complication of typhoid fever. It was observed eleven times in the Johns Hopkins cases, 0.7 per cent. It occurred during the latter part of the disease or in convalescence. It may be multiple or local.

Relapse occurred in 172 of the 1,500 Johns Hopkins cases, 11.4 per cent., and in 2,493 of 28,057 collected cases, 8.8 per cent. The apyretic interval between the primary attack and the relapse varied from six to forty-three days. The predisposition to relapse appears to be greater after mild primary attacks, and vice versa. The relapse may be protracted or there may be several relapses, up to five, and the total duration of the illness may then reach one year. Intercurrent relapse is fairly common. It may be protracted and severe. The death rate is higher than that of an ordinary relapse. The frequency of relapses is variously stated by different authorities. According to Dreschfeld (loc. cit.) Murchison places the percentage at 3, Griesinger at 6, Curschmann at from 6 to 12, and Shattuck at 16.

Typhoid Bacilli in the Circulating Blood.—Buxton (*American Journal of the Medical Sciences*, Vol. CXXXIII, 1907) in a study of 1,602 cases of typhoid fever found typhoid bacilli in the circulating blood, in 75 per cent.—in 89 per cent. during the first week, in 73 per cent. in the second week, in 60 per cent. in the third week, in 38 per cent. in the fourth week, and in 26 per cent. after the fourth week; as well as in 80 per cent. of relapses. Accord-

ing to Coleman and Buxton (*Journal of Medical Research*, Vol. XXI, 1909), typhoid bacilli have been recovered from the circulating blood as late as the eighth week of the disease and during convalescence. They explain the presence of the bacilli in the blood during the course of the disease by an overflow from the organs—principally spleen and lymphatic glands—in which they multiply, and they attribute many of the symptoms to the reaction on the part of the host to the endotoxins set free as a result of destruction of the bacteria. As the patient recovers fewer bacteria find their way into the blood-stream, and the symptoms lessen in severity. At the time of defervescence the blood ordinarily contains few bacilli or none. The persistence of symptoms not due to complications is attributed to continued growth of the bacilli, and the occurrence of relapse is explained by renewed multiplication of the bacilli in each instance with escape into the blood.

THE WASSERMANN REACTION.

A BRIEF STATEMENT OF SOME OF ITS PROVED PRACTICAL VALUES TO SOCIETY.

By JOHN BETHUNE STEIN, M.D.,

NEW YORK.

PROFESSOR OF PHYSIOLOGY AT THE NEW YORK COLLEGE OF DENTISTRY, INSTRUCTOR IN GENITOURINARY DISEASES IN THE COLLEGE OF PHYSICIANS AND SURGEONS (MEDICAL DEPARTMENT OF COLUMBIA UNIVERSITY).

The diagnosis of syphilis is of vital importance to the individual, the family, and society, but in a large majority of cases is most difficult, as the manifestations resemble those of other diseases or are unrecognizable and latent. In addition to the clinical diagnosis of syphilis and the diagnosis *ex juvantibus* (by palliative therapeutics) three other important methods of determining the disease have recently been discovered. They are in order of their discovery: (1) Diagnosis by means of inoculation experiments; the infection of apes and rabbits by the syphilitic virus. (2) Microscopic diagnosis. (3) Serodiagnosis of Wassermann, Neisser, and Bruck.

The clinical diagnosis is and will naturally remain of the greatest importance. The diagnosis *ex juvantibus*, in which the physician gives the patient antisyphilitic treatment in order to determine by its effect whether or not the disease is present, no longer plays the rôle it did. For this we are indebted to the Wassermann reaction and the detection by means of the microscope, especially the dark field illuminating apparatus, of the *Treponema pallidum*.

Occasionally the diagnosis *ex juvantibus* is made in a doubtful affection, for example, a tumor of the tongue, which is not affected by antisyphilitic treatment although the patient's serum gives a positive Wassermann reaction. A careful microscopic examination before prescribing antisyphilitic treatment would have determined the presence of the *Treponema pallidum*, the tubercle bacillus, or carcinoma cells in the lesion. In such a case we are dealing with a syphilitic individual and a non-syphilitic affection of the tongue, possibly a tuberculous or cancerous tumor of that organ.

The serodiagnosis of syphilis was introduced into the practice of medicine by Wassermann in 1905. It is the application to syphilis of a method for the deviation of the complement which was discovered by Jules Bordet and Octave Gengou in 1901. Widal calls it the "reaction of fixation." The reaction is specific and shows the presence of the syphilitic virus. If the causal agents are destroyed in the host the reaction will sooner or later become negative. The reaction is usually not positive until the seventh week after the appearance of the chancre, although it has been found positive 4 to 6 weeks after the infection.

The non-syphilitic nature of a suspected primary lesion is not proved by a negative reaction. A negative reaction in an untreated suspected case, there being no primary lesion manifest, makes the diagnosis of syphilis improbable, but not positively negative, because it may be broadly stated that only about 95 per cent. of cases of secondary and tertiary syphilis give a positive reaction.

Untreated secondary syphilis usually gives a positive reaction which is stronger than in treated cases. Treated secondary syphilis usually gives a positive reaction if the clinical symptoms are present. There are cases of secondary syphilis giving a negative reaction, which, on repeating the test (7 to 14 days later), becomes positive.

Untreated tertiary syphilis always gives a positive reaction, but in treated cases the reaction may be negative or weaker than in the treated ones. A gumma always gives a positive reaction (at times only moderately strong) by the method of Landsteiner, Müller, and Pötzl.

Latent syphilis often gives a weak reaction: 30 per cent. incomplete, 20 per cent. positive, and 50 per cent. negative. Untreated cases of latent syphilis are more likely to give a positive reaction, whereas with well treated cases the positive reaction is less frequent and weaker. In nervous diseases, including tabes dorsalis, about 10 per cent. are negative, 20 per cent. incompletely positive, and the remainder positive. The fact that tabetic patients who have never been treated for syphilis always give a positive reaction tends to support the theory that syphilis is the only cause of tabes. Cases of tabes where the syphilis has been previously treated give a weak positive or entirely negative reaction.

According to Müller, it is necessary to be very careful in making a diagnosis of lues cerebri, especially if there is a weak positive reaction or even a distinctly positive one. In such a condition of suspected lues cerebri a resort to a diagnosis *ex juvantibus* is necessary, and then a test of the patient's serum again. Both glioma and carcinoma of the liver may give a weak or positive reaction.

With dementia paralytica the reaction is always positive, therefore every paralytic is a "treponema carrier," a statement substantiated by the fact that rarely, if ever, is a primary lesion seen in a paralytic. In congenital syphilis the positive reaction is stronger than in other forms.

Specific treatment makes possible the conversion of a positive to a negative reaction and this is easier in the first stages of the disease (first three years). In dementia paralytica it is impossible to change by treatment a positive to a negative reaction. It should be remembered that if a positive reaction is present with clinical manifestations of the disease these manifestations disappear before the reaction becomes negative. The influence of the treatment upon the reaction is indirect. The reaction becomes negative because of the great destruction of spirochetes. A positive reaction after successive negative reactions has the same meaning as a clinical manifestation of syphilis.

The serum of the patient should be examined at frequent intervals during the course of whatever treatment is employed, in order to ascertain how the treatment affects an important symptom of the disease, viz., the deflection of the complement. If after a thorough course of treatment, however long, the Wassermann reaction is still positive, the treatment must be continued.

It sometimes happens that in a case that has been under mercurial treatment a negative reaction becomes positive. This phenomenon is analogous to those clinical syphilitic manifestations which may appear during the course of treatment. In such cases we are probably not dealing with mercury-fast spirochetes, but it is the method of treatment which is not efficient. After a single intravenous injection of salvarsan the positive reaction becomes negative much more rapidly than after a long course of mercurial treatment.

The prognosis is unfavorable in those cases which, in spite of antisyphilitic treatment, still show persistent positive reactions, such reactions being usually the forerunner of dementia paralytica. It is doubtful whether there are any cases in which the serum, after a proper treatment by mercury or salvarsan, does not give a negative reaction. But a single Wassermann test showing a negative reaction has no prognostic worth. It is only good for the time when it is made. If, however, the reaction remains continuously negative for a number of years, and there are no manifestations of syphilis, the prognosis is favorable, and the treatment may be discontinued. In such cases the patient's serum should be from time to time examined, and if a positive reaction occurs treatment should be at once renewed.

A few instances in which the Wassermann reaction is of great importance are in neurology and psychiatry, where the positive reaction of the blood serum and the cerebrospinal fluid after lumbar puncture, combined with the globulin reaction (Nonne-Apelt) and the cytodiagnosis (Nissl), are considered of great value, in the differential diagnosis of liver and kidney diseases, in cases of aneurysm, especially of the aorta, where the reaction is always positive, in cases of arteriosclerosis and aortic insufficiency, in which in their early stages the reaction is generally positive, and in the differential diagnosis of malignant tumors, tuberculosis, eye lesions, etc. It should be remembered that the Wassermann reaction is not a local but a constitutional reaction and that scrapings or an excised part of the tumor should be examined in addition to the blood serum.

Two old laws have been disproved through the Wassermann reaction, viz., (1) Colles law, that the mother of a syphilitic child is immune to syphilis, *i.e.*, is healthy; (2) the Profeta law, according to which the child of a syphilitic mother is immune to syphilis. But the Wassermann reaction demonstrates that in the former case the mother and in the latter case the child are syphilitic, both giving positive reactions, and therefore only appearing immune.

Syphilitic children often have no obvious symptoms of lues. The Hutchinson triad (notched teeth, otitis, interstitial keratitis) is not often seen. In fact, syphilis in children is often indicated only by a simple anemia or some slight nervousness.

A physician who recommends a wet nurse without first having her blood serum examined may be said to be almost criminally negligent.

The estimate that the death of 33 per cent. of syphilitics occurs prematurely, due to the sequelæ of the luetic infection, indicates the great importance of the Wassermann reaction in life insurance.

In forensic medicine the Wassermann will likely play an important part, for the evidence of the specific reaction of the blood serum or cerebrospinal fluid may be more convincing to a judge and jury than that deducted from a discussion of psychiatrics in court.

Inasmuch as a positive reaction proves the presence of living spirochetes in the patient's body, every individual whose serum shows a positive reaction should be immediately treated for syphilis, not only as a prophylactic measure for himself against the sequelæ of the luetic infection, but also that he may not be a menace to his family and society.

The blood serum of nervous and anemic children as well as, of course, that of every syphilitic about to enter the marriage state should be examined as to its reaction.

The writer's experience in Dr. Rudolph Müller's laboratory, in the Serodiagnostic Station (the first established in the world) at the University Clinic of Professor Finger in the Allgemeines Krankenhaus, Vienna, where, by Dr. Müller and his assistants, over 36,500 cases had been examined up to September, 1911, convinced him that *the great practical value to the masses of the Wassermann reaction can be obtained only by the establishment in the health department and large clinics of our cities of similar central serodiagnostic stations.*

To these stations would be sent for examination the serum of inmates not only of orphan asylums, as in Vienna, but also of insane and other asylums, reformatories, prisons, dispensaries, hospitals, and other similar public institutions, which would be used as controls for cases where syphilis is known or suspected to exist.

Inasmuch as among the inmates of our public institutions sending serum, the existence of many cases of latent syphilis will also be discovered through the use of these controls, the inestimable benefit to society resulting from the operation of such central serodiagnostic stations is obvious.

126 West Seventieth Street.

AMEBIC DYSENTERY.

By ALBERT F. R. ANDRESEN, M. D.,

BROOKLYN, N. Y.

That amebic dysentery is not exclusively a tropical disease has become generally accepted in recent years, and typical cases of this specific form of colitis have been reported by observers as far north as Montreal, Canada, and even Alaska, in patients who have never left their respective communities. It is, therefore, necessary that the practitioner in the more northerly States should become familiar with this disease, and be enabled to afford relief and prevent serious complications in many cases of intractable diarrhea.

The ameba was first suggested as the cause of dysentery by Lambl in 1859, and since that time much discussion has been indulged in concerning the specificity of this organism. As late as November, 1910, Tanaka[1] suggested that there must be an organism which attacks the bowel mucosa first, and prepares a point of lessened resistance for invasion of the ameba, it being a well-known fact that amebæ are found at times in the feces of individuals who have never suffered from any symp-

toms of dysentery.[8] Efforts have been made to differentiate pathogenic from non-pathogenic forms; the former, the entameba histolytica, being described as having a more strongly refractive ectoplasm and a smaller amount of chromatin in its nucleus than the non-pathogenic entameba coli. Most observers are now agreed that this differentiation is unnecessary, pathogenic amebæ being able to remain in the bowels for years without causing dysenteric symptoms, until the bodily resistance is weakened by disease, pneumonia and tuberculosis being often the exciting cause. The ameba has so far not been isolated, as it grows only in symbiosis with other organisms. Contaminated water seems to be the principal carrier of infection, but green vegetables which have been fertilized with human excreta are also a common source of infection.[9]

Amebic dysentery is a colitis characterized by the presence of a large or small number of ulcerations of the bowel mucosa. The ulcers are of different sizes, and the edges are undermined. They are found mostly in the rectum and sigmoid, less frequently in the splenic and hepatic flexures, and even in the ileum. They rarely progress to perforation, and profuse intestinal hemorrhage is uncommon, but in 5 to 10 per cent. of cases infection spreads to the liver, producing amebic abscess of that organ. These abscesses are usually multiple and may perforate into the pleura, pericardium, or any of the neighboring abdominal organs. Other intestinal parasites[4] frequently found complicating amebiasis are strongyloides, cercomonads, teniæ, etc., and may confuse the diagnosis.

The symptoms vary considerably, there being usually a more or less severe diarrhea, but occasionally constipation. The onset may be abrupt or gradual; when abrupt being characterized by frequent purging—as many as six or eight scanty, liquid, mucous, bloody stools in an hour—with severe abdominal pain and tenesmus. There is extreme prostration, the pulse becomes rapid and feeble, and there is a moderate febrile reaction. In these acute cases the patient becomes rapidly emaciated and may die within a week, but such a severe onset is rare. The usual type of case, especially in the northern climates, has a gradual onset, with occasional attacks of diarrhea with or without tenesmus, sometimes alternating with constipation. The stools are very offensive, usually contain mucus, and may or may not contain some streaks or flecks of bright blood. There is not, as a rule, very much loss of weight, but considerable weakness is usually complained of. Gastric symptoms are not often present, the patient being frequently able to eat fairly large meals without discomfort. There may be pain in the region of the liver and occasionally slight jaundice.

Physical examination: Emaciation is not usually extreme, but the skin has a pallor like that of malignancy and has a putty-like feel. The tongue is coated and furred. The abdominal wall is flabby and there is usually tenderness over the colon, worst over the cecum and sigmoid. The liver region may be slightly tender, and there may be some enlargement of that organ, even in the absence of hepatic abscess. Considerable enlargement of the liver, especially where associated with irregular chills and fever, indicates the presence of that dangerous complication. Proctoscopy reveals the presence of ulcerated patches in the rectum and sigmoid, scrapings from which, examined microscopically on a heated slide, will disclose red and white blood cells, epithelium, mucus, and numerous large motile amebæ, many of them containing red blood cells. The same elements may be found in a warm specimen of stool, preferably after a saline cathartic has been administered, but the above method is more reliable. The blood findings are not characteristic, being commonly only those of the complications. The diagnosis of amebic dysentery can be established only by the finding of motile amebæ, some containing red blood cells, in the stool or in the scrapings from the ulcers. It is thus differentiated from colitis due to other causes, such as bacillary dysentery, the diarrhea of nephritis, hepatic cirrhosis, achylia gastrica, and intestinal tuberculosis or malignancy. The diagnosis of the complications does not differ from that where the same conditions are due to other causes.

The prophylaxis is obvious and should be directed toward the improvement of the water supply, the prevention of human fertilization of green vegetables, and the careful disinfection of the excreta of persons known to be infected. Early treatment will prevent complications and should be instituted as soon as the diagnosis has been made. Various methods of treatment have been suggested and excellent results have been reported by the exponents of each method. Deeks and Shaw,[2-3] at the Ancon Hospital, Panama, recommend milk diet, a preliminary dose of castor oil, opium for pain and tenesmus, colonic irrigations of saline solution, and bismuth subnitrate in one-half teaspoonful (one dram by weight) doses every three hours for from three to fifteen days. They claim a large percentage of cures. Hanes[5] of Kentucky has recommended a liberal nutritious diet, opium as necessary, little or no medication by mouth, and pins his faith on filling the large bowel daily with coal oil, three to five pints, preceded by a simple cold enema of quinine solution. Other forms of treatment which have been used are large doses of bolus alba by mouth,[7] kho-sam,[6] the remedy of Cochin China, and all kinds of colonic irrigations. In stubborn cases appendicostomy followed by irrigations through the appendix has been done with good results.[10]

The best treatment, however, and that which has proved most successful in the hands of most clinicians, has been the ipecac treatment, which I shall give in detail. In my limited experience with two cases, in one of which I tried the first two methods outlined above and had recurrences, I have found this treatment to be really wonderful in its results. The ipecac treatment is the one which has been in use in India for many years, and is now in use in the Philippine Islands. It consists in giving large initial doses of ipecac and gradually reducing the dose until symptoms are gone. The patient is best put upon a liquid diet, or a light diet leaving a slight residue, and at first is kept in bed. An initial dose of castor oil is administered, and twice daily cold enemata are given, either saline, quinine solution, 1 to 500, or thymol, 1 to 2,000, being used. The cold enemata greatly relieve the tenesmus and wash out débris, but it is almost certain that antiseptics locally used have no effect on the ameba in the colon. The ipecac is best given in the form of 5-gr. salol-coated or keratin-coated pills. A pill larger than the 5 gr. is very difficult to swallow and will, probably, pass the pylorus with difficulty. The best time for giving the ipecac is in the evening, about 8 o'clock, and nothing should be eaten for four hours before. It is usual to precede the ipecac twenty minutes by a dose of tincture of opium (about

twenty minims). The initial dose of ipecac is large, Simon recommending as much as 40 or 60 gr. I have found that excellent results are obtained with 30 to 40 gr. as the first dose. Although large doses are, strange to say, more readily tolerated by the stomach than smaller ones, it can readily be appreciated how a debilitated patient will feel if told to take a dozen large pills at one time. If the pills are properly coated the patient may not vomit at all, or may vomit a little clear mucus after three or four hours, probably the effect of absorption of the emetine in the ipecac. Vomiting can be combated by ice-bags to the throat, mustard paste to the epigastrium, and morphine given hypodermatically.

The dose is reduced 5 gr. every evening until 10 gr. is reached, when it is well to continue the 10-gr. dose for a couple of weeks. At times there is considerable nausea or vomiting after the smaller doses, and in these cases it is better to give the smallest dose tolerated for the last two weeks. Under this form of treatment the diarrhea stops within a day or two, and scrapings made from the rectum as early as forty-eight hours after the first dose fail to reveal the ameba. The ulcers heal often in less than a week. P. M. Ashburn, U. S. A., at a meeting of the American Society of Tropical Medicine, made a statement that if he can not cure a case of amebic dysentery in one month by the ipecac treatment, it is doubtful if a cure is possible.

After the first two or three weeks of treatment a more liberal diet is allowed and the patient should gradually return to a regular diet. The first week or ten days should be spent in bed, but after that the patient can be up during the morning and early afternoon, retiring about 4 P.M. Where the treatment is thoroughly carried out, complications are rare,[11] and return of the condition after months or years is much less common than after the other methods of treatment. At the present time the ipecac treatment is the one to be recommended, but it is to be hoped that some day, when the ameba is grown in pure culture, a serum or vaccine may be elaborated which will effect a speedy and permanent cure.

28 SIXTH AVENUE.

The Precancerous Stage.—Parker Syms states that in a very large proportion of cancers there has been a purely and distinctly precancerous stage. By this is meant that one can recognize certain lesions, certain benign growths, and certain abnormal conditions, as the precursors of cancer. This is one of the most hopeful phases of the present knowledge of cancer.—*New York State Journal of Medicine.*

ANESTHESIA DON'TS.*

By JOSEPH E. LUMBARD, M.D.,
NEW YORK.
ANESTHETIST TO THE HARLEM, THE GENERAL MEMORIAL, THE RED CROSS, AND THE LYING-IN HOSPITALS, MEMBER A.M.A. FELLOW N. Y. ACADEMY OF MEDICINE.

General.

1. Don't use ether or chloroform that is not transparent, colorless, neutral in reaction, or which leaves a residue upon evaporation.

2. Don't forget that the selection of the proper anesthetic is as important as its administration.

3. Don't forget that it is always your duty to use the safest anesthetic at your command.

4. Don't use an inhaler which cannot be sterilized.

5. Don't let convenience preclude safety in the selection of chloroform instead of ether, or ethyl chloride instead of nitrous oxide.

6. Don't forget that morphine, if properly used in well selected cases, especially in alcoholics and athletes, is a valuable adjunct to a smooth narcosis, but should be given at least one-half hour before beginning the anesthesia.

7. Don't assume because your patient has been anesthetized once without bad results that you do not have to be on the alert in future administrations.

8. Don't forget there may be danger although the patient has no organic disease.

9. Don't forget that the excessive use of tobacco will often prevent a smooth narcosis.

10. Don't always expect a smooth anesthesia with patients who are "bad travelers" on land or sea.

11. Don't forget that no one anesthetic will do for all cases under all circumstances.

12. Don't be governed by percentages or the amount of anesthetic used, but by the condition of the patient.

13. Don't forget that the respiration is the most important thing to watch, no matter which anesthetic is employed.

14. Don't forget that the depth of respiration is the most trustworthy of all signs.

15. Don't forget that the greatest factor in safety lies with the experience of the anesthetist more than with the anesthetic or inhaler used.

16. Don't forget that there is always a chance for any patient to act badly and possibly die under the anesthetic.

17. Don't forget that oxygen added to ether or chloroform will often make a narcosis safe that would not be so otherwise.

18. Don't forget that it is easier (and much safer) to add to than to subtract from when administering anesthetics.

19. Don't be afraid to give anesthetics in chronic cardiac, pulmonary, and renal conditions.

20. Don't forget that most trouble in the administration of all anesthetics comes from using too much.

21. Don't forget that the color of the ear is a very good guide for the beginning of cyanosis.

22. Don't resort to intratracheal or rectal anesthesia when simpler and safer methods will accomplish the same purpose.

23. Don't expect to relieve mechanical obstruction in the respiratory tract by hypodermics.

24. Don't watch the operation, even if you can do so without neglecting your patient; it does not inspire the surgeon's confidence.

*Read before the Washington Heights Medical Society, October 24, 1911.

25. Don't attempt to secure deep anesthesia in empyema cases; use just as little of the anesthetic as possible.

26. Don't forget that surgical shock may apparently deepen the anesthesia and cause alarming symptoms.

27. Don't forget that it is illegal to have a nurse administer an anesthetic in the State of New York.

Chloroform.

1. Don't let the surgeon hurry the anesthetist, especially when using chloroform.

2. Don't have too much covering on the mask when giving chloroform. Always give the patient plenty of air.

3. Don't administer chloroform with the patient in the sitting posture.

4. Don't advise long or deep inspirations when using chloroform.

5. Don't forget that the majority of deaths under chloroform have occurred during the first period of its administration.

6. Don't forget that while the toxic effects of chloroform often show themselves very suddenly, they may be delayed for days.

7. Don't assume because you have used chloroform with good results in obstetrical cases that you may use it promiscuously in all other cases. Chloroform is not free from danger in obstetrical cases.

8. Don't use chloroform in obstetrical work when the uterine contractions are feeble and the fetal heart cannot be heard.

9. Don't use chloroform in a small room lighted by gas.

10. Don't lose sight of the eye reflexes when giving chloroform.

11. Don't administer chloroform by a closed inhaler.

12. Don't charge a patient up with chloroform, as is so often done.

13. Don't use chloroform for the removal of tonsils and adenoids.

14. Don't forget to add a few drops of ether when using chloroform.

Ether.

1. Don't forget that ether is a stimulant, while chloroform is a depressant.

2. Don't forget that ether usually gives warning of approaching danger which chloroform is not apt to do.

3. Don't forget that ether has a larger latitude for safety than chloroform; but do not abuse it.

4. Don't rely on this comparative safety of ether and allow its administration by a novice unless absolutely necessary.

5. Don't forget, generally speaking, that ether is much safer than chloroform and certainly should have first choice; other things being equal.

Nitrous Oxide.

1. Don't be alarmed at slight cyanosis when using nitrous oxide.

2. Don't forget that jactitation, when using nitrous oxide, calls for more oxygen.

3. Don't forget that nitrous oxide can be given safely at any age.

4. Don't forget that nitrous oxide and oxygen is the safest anesthetic known, but it is not always satisfactory to the surgeon.

5. Don't fail to have a witness when inducing anesthesia, especially when using gas. Many lawsuits have resulted because this precaution was not taken.

6. Don't forget to empty the bladder before giving gas to children, as they often urinate while under its influence.

7. Don't forget that nitrous oxide is the safest anesthetic for short operations and examinations.

8. Don't expect a good anesthesia when using nitrous oxide on alcoholics.

Relation to Patient.

1. Don't starve or purge a weak patient too much prior to anesthesia.

2. Don't forget to secure the patient's confidence before commencing the administration of the anesthetic and begin very slowly and quietly. Allow neither talking nor noise in the room. You will thus contribute to a smooth narcosis.

3. Don't forget to ask the patient if he is accustomed to sleep with his head high or low, and govern yourself accordingly when administering the anesthetic.

4. Don't forget that the nose, mouth, stomach, bowels, and bladder should be empty before beginning anesthesia.

5. Don't forget to have teeth, nose, and buccal cavity clean before giving the anesthetic.

6. Don't forget to keep the patient warm at all times.

7. Don't forget to wash out the stomach when it is full. The anesthetic will act more quickly and more safely.

8. Don't forget that the change of posture may add greatly to the patient's comfort and safety.

9. Don't forget to give a drug fiend his usual dose before anesthetization.

10. Don't worry about the pulse if the respiration and the color of the face are satisfactory.

11. Don't be alarmed when the pulse is a little weak or rapid. Look for the cause and remedy it.

12. Don't go over the safety line in trying to relax the abdominal muscles in acute conditions.

13. Don't forget to withdraw the anesthetic immediately when you have a widely dilated pupil, fixed eyeball and eyelids partly open. This means that too much has been given.

14. Don't forget that a dilated pupil with a moving eyeball means that not enough has been given.

15. Don't forget to drain the mucus from the mouth by means of a gauze wick or suction apparatus.

16. Don't deceive children about to be anesthetized.

Don't forget, first, last, and all the time, to keep your whole attention fixed on the administration of the anesthetic.

Graham Court, 1925 Seventh Avenue.

APHONIA.

By E. HARRISON GRIFFIN, M.D.,

NEW YORK.

Case I.—Mr. A., age 23, accompanied by his mother, was brought to my office by his family physician, who gave the following history. The patient had lost his voice completely and had been unable to utter a word for the past year. The loss of voice had come on suddenly and he had been examined by physicians in San Francisco, Chicago, St. Louis, and New York, who had diagnosed his trouble as paralysis of the vocal cords, laryngeal

phthisis, tumor of the larynx, and various other diagnoses were given.

The patient was a well-built man, had broad shoulders, a deep chest, and the perfect appearance of health. His family physician explained to me privately that the patient was very anxious to recover his voice as he wished to be married. He had applied to every physician whom he knew, had been treated with electricity, cod liver oil, and creosote, and had run the gauntlet of the rest of the pharmacopeia. His larynx had been sprayed, local applications had been made, and still the voice had not been restored. He had run the drift of the physicians of his friends, but still he could not talk.

An examination of his larynx was made with a little difficulty, for he wanted to stop me every moment to write something in the way of an explanation on paper. The examination showed the vocal cords normal in color, with perfect motion, but with a slight defect which I shall describe later. There was absence of any swelling or ulceration, indicating phthisis, syphilis, or cancer. There was no sign of a polypus, papillomatous growth, or of other tumor. The base of the tongue was free from any lingual tonsil. There was no foreign body, and there was no sign of paralysis. In other words, his larynx was normal. The patient complained of pain in the examination, but the condition of the membrane showed that the pain was more mental than actual. By exclusion I diagnosed the condition as one of hysterical aphonia.

I sprayed the larynx and passed probes into it, and, like all the various other medications the larynx had received, all of my efforts were futile. The patient only looked at me with a dogged and vacant stare, as much as to say, "I have tried everybody; what can you do more than the rest?" I was becoming interested in my negative victory. The family physician had told me that the patient wished to be married. I leaned back in my chair, after an unsuccessful medication of his larynx, and suddenly patted my patient on the shoulder; I looked him full in the eye and asked him suddenly if he did not know "a pretty girl, one of those nice girls, one with pretty eyes and pretty mouth;" if he did not want to be married. I had his attention in a moment. I now told him to watch my lips and to say "A." I repeated "A," but the patient was unable to shape his lips to produce any sound excepting a gurgle. I looked my patient in the eye and told him that when he left my office his voice would be as perfect as mine. I told him that I would not see another case and would keep him in my chair all day, but when he left he would leave with a perfect voice. This was rather a strenuous prognosis for a patient whose voice had been lost over a year and whose larynx had received all manner of medication without avail.

I worked with him as if he were a child. I showed him how to form his lips, where to place his tongue, when to take a full breath, and when to try to talk. After one hour I had kept my promise. I had his voice restored, and he was talking to me as perfectly as any one. I wrote a prescription for twenty grains of quinine at bedtime and one-sixtieth of a grain of strychnine after each meal. I was about to dismiss him, when, in the presence of the family doctor, he gave the following history. He had been a "dope fiend," as he called himself, smoking opium and also taking it hyperdermically. He had left New York so as not to disgrace his family and had gone to California, where he was called "the dope." One day he met a Christian girl, with whom he fell in love. He was a Hebrew. She cured him of the morphine habit. He came East to obtain the consent of his parents to his marriage. During his absence his sweetheart got in trouble with another man and, to cover up her mistake, married him. When her former fiancé heard this, the shock made him lose his voice.

The happy therapeutic result may be attributed to the fact that I was positive of my diagnosis, which was made by exclusion in a case that gave a highly colored history, showing an erotic and a neurotic temperament. Hysterical aphonia is a very common affection and is liable to be overlooked. The following case came under my observation some years ago.

Case II.—Miss B., age 22 years, and employed as a seamstress in a cloak factory, had lost her voice suddenly. She had been in the best of health and in the middle of the day had taken a nap on a sofa. When she awoke she was unable to talk. She was a well developed girl and seemed rather phlegmatic than neurasthenic. She was very anxious to regain her voice, she wished to change her occupation to one in which the use of the voice was indispensable. Her voice had been lost for over six months and she had run the gauntlet of the various clinics. Her condition had been diagnosed as paralysis, tumor of the cord, laryngeal phthisis, etc., in fact every every diagnosis had been made in which aphonia might be a symptom. An examination of the larynx was negative. I failed to find any paralysis or tumor, or any sign of laryngeal phthisis; nothing denoting a syphilitic lesion and no manifestation of a cancerous degeneration. There was a slight space between the cords when they closed at the arytenoid commissure junction, a sure sign of hysterical aphonia. She wrote on a piece of paper that she could sing perfectly although her speaking voice had entirely been lost. I asked her to sing and she rendered a little song in perfect time and in the right key and full of harmony. I started to take her history and was rather annoyed at the time she took to write answers to my questions, when I turned suddenly and told her to sing the answers. "Listen," said I, "take this tune." Her answers came almost as quickly as my questions. "Listen," I said again, when I changed my tune, "answer me in the same key." I varied the tone until I had her interested, when I spoke to her in the speaking voice. She answered me in the speaking voice. I shot question after question in this normal speaking voice and was answered in the normal speaking voice. I clapped her on the shoulder. "Fine," I said, "you are speaking splendidly." She stopped on the instant; her voice was lost at the word speak. She wrote on her pad, "I cannot speak."

Here was a case in which the patient was apparently removed to another atmosphere; she could talk without the slightest impediment when she thought she was singing; but at the mere mention of the word "speak" her voice became a blank. I drilled this case for a few visits until this word failed to arouse any terror in her and she regained her voice completely.

Fright will at times produce almost complete loss of voice. Overanxiety will do the same, as illustrated in the following case:

Case III.—Male, age 26, actor, had played

around New York for years, but never in New York, and was solicitous to have his voice in good shape at his first appearance. I examined his larynx at about ten o'clock one morning and he left my office feeling, as he expressed it, "fine." At seven o'clock that evening he came in to see me and in a whispering voice asked me for a note to his manager, stating that he would not be able to play as he had lost his voice. I knew that there was nothing that could produce this sudden loss of voice in his case except fright and overanxiety on his part. I spoke to him rather sharply and said something rather disagreeable. He was provoked in an instant and spoke out in a loud voice, "You are wrong, doctor, you are wrong." I only wanted to show him that he could talk. He asked me to spray his throat. I told him that this was not necessary. He asked me to just look at it. Again I refused. "Will my voice last?" "Certainly," I said. "Go on with the determination that you are going to succeed and you can laugh at the audience. You will not have any trouble." I heard this man open the play that night at eight-fifteen o'clock and every word was as plain as possible. Still at seven he had not been able to say a word.

If these cases are not diagnosed correctly at first the patient instead of improving may lose his voice completely or be able to converse in a very low whisper, when suddenly some shock or responsibility may restore the voice as mysteriously as it disappeared. These cases are all interesting, as they are liable to present themselves to the specialist only after having been labeled with every diagnosis possible except the correct one. The loss of voice becomes a habit and in some cases the voice is restored only after the most strenuous medication. The correct diagnosis is first essential, then we should bear in mind that we have to teach the patient to talk as a parent would teach a child. When the patient notes that he can utter, if only a few words, the rest of the cure is simple.

55 West Forty-seventh Street.

AN IMPROVED SUBMUCOUS KNIFE.

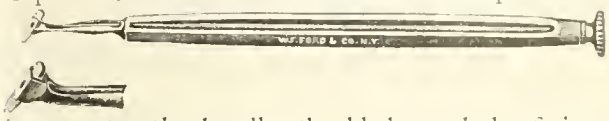
By JOSEPH COLEMAN, M.D.

NEW YORK.

Those who have had considerable experience in the performance of the submucous operation upon the nasal septum have come to regard two steps in the procedure to be of extreme delicacy and at the same time of the greatest importance; namely, the primary incision through the mucous membrane and perichondrium, and later the incision through the cartilage. The performance of these two steps has always been looked upon as a sort of "bugbear" since the inception of the operation, first on account of the importance of making these incisions through just the proper structures, and second on account of the difficulty of their execution. Perhaps the one most important step is the primary incision, for, while probably not so delicate a procedure as the incision through the cartilage, its great importance lies in the fact that if the incision is not deep enough to extend not only through the mucous membrane, but also through the perichondrium and down to the cartilage, the separation of the flap becomes extremely hazardous and difficult, in fact, almost impossible without its consequent tearing.

For the safer and more easy performance of these two steps, the incisions through the membrane and through the cartilage, I have devised a knife, using the principle of the adjustable blade as in the instrument of Dr. John McCoy of New York. A blade that is adjustable to cut to a certain depth, and that cannot possibly cut any deeper, is the greatest safeguard an operator can have. The blade is adjusted according to the thickness of the septum as measured by the fingers or the septometer, being about ⅛ of an inch for the primary incision through the mucous membrane and perichondrium, and 1/16 of an inch for the incision through the cartilage. The essential difference between this knife and the one devised by Dr. McCoy is the absence of the set-screw in the head. It was found that in many cases traumatism was caused by the screw head making the membrane friable and causing bleeding, or it would even cause a second incision, behind and parallel to that made by the blade.

To overcome this, the writer has devised a knife doing away with the exposed set-screw and its consequent disadvantages. This has been done by having the set-screw placed in the handle of the instrument, where it is completely covered and can cause no possible harm. The instrument is composed of



three parts—the handle, the blade, and the fixing rod. The fixing rod fits into the handle, which has been hollowed for it and engages the blade, which fits into a slot made for it in the head of the handle. The head of the handle holding the blade is tilted outward at an obtuse angle from the handle, so that when using the cutting edge of the knife at right angles to the septum the hand of the operator is out of the line of vision. The instrument is made so that every part is readily accessible and may be easily cleaned and dried.

The ordinary method of using a plain scalpel or a knife whose cutting depth cannot be regulated is to be deprecated on account of the danger of the manipulation and the extreme delicacy in its performance. We must remember that the safety of the flaps and the prevention of perforation depend upon this manipulation. The use of a knife such as the writer has devised does away with the extreme delicacy of making the incisions and the liability of perforating the septum or destroying the membranes, and he feels, therefore, that by its use the technique of the submucous operation is improved. The knife has been made for use by the W. F. Ford Co. of New York City.

59 West Ninetieth Street.

Technique and Indications for Gaseous Injections in the Treatment of Pleural Effusions.—Lemoine advocates the use of gaseous injections in pleural effusions and gives the technique and the indications for their use. In serofibrinous pleurisy they are indicated in abundant effusions, when they are to be drawn off. If all the fluid be removed at once the sudden expansion of the compressed lung tissue does harm, but if we partially replace it with air or oxygen the expansion is less rapid. In chronic recurring pleurisy, resulting from tuberculosis, the injection of air has a similar effect to the entrance of air into the peritoneum. In pleurisy, in which a portion of the fluid flows out on aspiration and then the exit becomes clogged, the entrance of gas causes the fluid to begin to flow again. In pleurisy, with large unilateral tuberculous lesions, oxygen introduced has a beneficial effect. In purulent pleurisy it is less useful.—*Le Nord Médical.*

MEDICAL IMAGINATION.

FEW, if any, of our human faculties have been more generally maligned and vilified in the common estimation than that known to psychology as imagination. The reason for this is not far to seek, for the average man thinks of imagination as concerned mostly, if not wholly, with unrealities, with fancies so far from the matter-of-fact as to be wholly false and useless. That many physicians partake in this unscientific way of viewing the function of imagination is inevitable, even though it imply the ignoring of the tremendously productive aspect technically termed creative imagination, mother of much of the world's real progress. Yet it is to a simpler phase of the process that we at present especially refer. Men are beginning nowadays to realize that nearly all medical "education" (referring to the preliminary routine of the schools) is too somatic, too one-sided—had it indeed, for generations not been so, Eddyism could never have received the credit it has sometimes won for stimulating the medical profession to recognize that the patient inevitably, man, woman, or child, has mind as well as body, "fire as well as clay." As the greatest of the world's wise men, philosophers howbeit classed as scientists, have so often emphasized, imagination is a very important element in the advancement of learning, even as it often is dominant in the production and in the cure of disease. To the physician himself imagination, rightly used and adequately, is invaluable. All the marvels of modern electricity, röntgen ray, and optics combined do not equip him for his work as does his own rightly used imagination.

Every kind of scientific understanding that the "doctor" has depends upon some phase of his imagination. Saying nothing about chemistry and physics (how little one could really know of these without imagination!) one learns anatomy, physiology, pathology, physical diagnosis, and all kindred fundamental subjects only as he extends the very limited facts that he can observe and read about with their imagined relations, applications and effects. No medical student "knows his physiology," for example, until he can (in imagination) look directly and with accurate eye to every nook and corner of his body and see just what is going on there —observing the movements both molar and molecular and comprehending their marvelous interdependence. If he use his imagination to the best advantage in doing this he will soon come to the conclusion, whether or not expressed aloud, that the undevout biologist, like the undevout astronomer, is mad. And to realize this is in itself much.

If so obviously important, nay quite essential, in the acquirement of the totalities of wisdom that furnish forth the competent physician, how could we say too much for imagination in the use of this learning? If the medical student requires imagination, the medical practitioner, student always, too, uses it "as hands and feet." The veriest quack that ever made a compelling contract with a newspaper can see the skin of his eager patients as well as the most "ethical" of his old "regular" contemporaries, but he lacks the knowledge by which his imagination can look within the skin and so discriminate a typhoid from a "near typhoid." One sees very great differences in this respect among medical colleagues who, to all intents and purposes, have the same kind and the same amount of professional knowledge, derived from the same books and cases under the same instructors and with essentially the same variety of patients. One of these men or women makes accurate diagnosis nine times out of ten and the other only pretends to do so. The one can look right through the tissues, see the conditions present in each whether right or wrong, and thereupon lay the plan of the case and its needful treatment; the other recalls only facts and principles more or less germane, but never for a single once exactly like those of the case in hand, and therefore never exactly applicable again. Only by the aid of the constructive and reproductive imagination can a physician comprehend the *totality* of conditions, which every case inherently is; only so can he understand and cure the patient rather than the case, as the commencement orator has long been so fond of wisely preaching, the man rather than his disease.

This power of looking through a patient's body systematically and carefully with the eye and ear and finger of imagination is an ability easily acquired by practice and easily retained and perfected by the miraculous facility of habituation. It is a wholly additional faculty, its acquirement taking nothing out of the mind, but rather adding much to it. It is in no sense opposed to the judgment or to the reasoning powers, for properly speaking these are impossible for practical purposes without dependence continually on the imagination; the new combination of things heard aand felt and seen and the new arrangement of these for the benefit of the case in hand. This habit of the systematic viewing of the organism is readily extendible to conditions of the mind as well, and here the practitioner must use his imagination and his practical psychology (knowledge of human nature) more broadly yet and be able to foresee the remote results of agencies producing their effects perhaps deep in the subconscious intricacies of the nervous system—just how a definite suggested idea will act on an over-balanced brain. This is imagination, too. Think of a power of vision able at once to see around corners and to magnify like the most recent oil-immersion objective, adapt this simile to hearing and then to touch, combine them, and let

them penetrate together into the inmost recesses of an organism wholly transparent and one can see (in imagination) something of the ability that this habit in question confers upon the properly equipped diagnosing physician. If the doctor, as an individual, has no imagination, let him acquire some; but if he has one, by all means let him see his privileged duty to use it, always to the common benefit.

FAT EMBOLISM.

It is probable that small quantities of liquid fat find their way into the venous system after every fracture of the larger bones, the veins in the marrow being so arranged anatomically as to remain wide open after being torn through. Usually, however, this occurrence leads to no recognizable symptoms and certainly does not introduce any serious element into the illness. Occasionally, however, whether because of the large amounts of fat entering the circulation or because of some individual differences in patients, fat embolism becomes the dominant complication of accidental or operative fracture. It is a number of such cases that form the subject of a valuable paper by Nils Gröndahl in the *Deutsche Zeitschrift für Chirurgie* (Band III, Heft 1-3).

Gröndahl considers that the cerebral form of fat embolism is the more important clinically, forming a fairly well-defined clinical picture and running no such stormy and rapidly fatal course as massive pulmonary embolism. He describes five fatal and five non-fatal cases of such embolism and deduces the following main points in the symptomatology of the condition. In cerebral fat embolism a free interval occurs between the first shock accompanying fracture and the appearance of cerebral symptoms. This interval varies in duration, extending even over several days, but usually it is not over four to eight hours long. The first symptoms are those of general depression of cerebral activity manifested by loss of memory, drowsiness, disorientation, slowness of mental processes, etc. Not infrequently signs of pulmonary embolism, such as dyspnea, cough, pain in the side, and bloody sputum, appear during this period, termed "the stage of stupor" by Gröndahl. In patients who finally recover, amelioration of symptoms begins at about this time; fatal cases, on the other hand, progress until the next or "comatose stage," which is marked by loss of somatic reflexes, deep stupor, and manifestations of cerebral irritation, such as spasms, contractures, and convulsions. Death is usually ushered in by deepening of the coma, development of paralysis, and gradual failure of respiration and circulation.

There are several possible cerebral complications of an accident such as fracture that must be differentiated from the cerebral form of fat embolism. Concussion is easily differentiated by the development of symptoms in immediate sequence upon the occurrence of the accident, a free interval not being present. Contusion and laceration of the brain usually show signs of focal irritation, which develop very early after the accident and are fully manifest almost from their onset. Compression of the brain, especially that consequent upon an extradural hemorrhage, is difficult to differentiate from embolism because of the well-defined free interval in this condition. The main symptoms here, however, are those of increase of intracranial pressure, shown by slowing pulse, irregular respiration, and especially progressive edema of the optic nerves, disclosed by the ophthalmoscope. Other pressure symptoms are likewise of gradual and progressive development, while fat embolism is characterized rather by the general lowering of cerebral functions than by symptoms of focal pressure. Diabetic coma, uremia, etc., should, of course, be excluded by examination of the urine for sugar, albumin, acids, etc., and by the absence of other signs of severe diabetes or nephritis.

In connection with the clinical study, sketched above, Gröndahl contributes a valuable pathological research, shows the occurrence of fat embolism in various minor injuries, and notes the distribution of fat in the various organs with the microscopic appearances encountered. So far as therapy is concerned, he is inclined to favor the suggestion made by Wilms that a thoracic duct fistula should be made as soon as the stage of stupor appears to be developing toward coma. He believes that the most dangerous fat emboli, because of size and quantity, reach the circulation through the lymphatics and may be stopped by the operation proposed. Gröndahl's interesting paper should stimulate clinical and pathological study of this condition, which is too often dismissed as too rare a complication to deserve serious consideration in the occurrence of cerebral symptoms after fractures.

EXPERIMENTAL APPENDICITIS AND RHEUMATISM.

The theory that in many instances appendicitis is caused by rheumatism was advanced by Beverley Robinson in the Medical Record, September 14, 1895. This theory was based on the observation that some of the milder symptoms of rheumatism occurred in patients who had had one or more attacks of appendicitis; that others had reported the occurrence of acute articular rheumatism either directly preceding or following evident signs of appendicitis; that rheumatism frequently attacked the pleura and pericardium, and might similarly attack the peritoneal covering of the appendix; that the suddenness of onset of rheumatism was characteristic also of appendicitis; and that antirheumatic drugs frequently relieved the symptoms of appendicitis. This hypothesis was based solely on clinical observation. Nevertheless, subsequent laboratory investigations seem to have shown that this relationship between appendicitis and rheumatism is not a fanciful one.

In 1901 Adrian was able to demonstrate, both clinically and experimentally, that appendicitis may be the result of a general blood infection. By means of intravenous injections of streptococci, staphylococci, typhoid bacilli, pneumococci, and colon bacilli, he succeeded in producing appendicitis in rabbits. In one of his experiments he isolated the pneumococcus from the inflamed organ.

F. J. Poynton and A. Paine (*Lancet*, October

28, 1911), to whom is accredited the discovery of the so-called *Diplococcus rheumaticus,* in continuing their investigations on the subject of rheumatism, have succeeded in producing appendicitis by means of intravenous inoculations of the diplococcus. The organism was isolated from the synovial fluid of the distended knee-joint of a boy suffering from rheumatism. Bouillon cultures of the diplococcus were injected into the veins of young rabbits. In addition to the production of multiple arthritis and mucous diarrhea, these inoculations, in the case of many of the animals, set up an inflammation in the middle two-fourths of the appendix. This was the only obvious alimentary lesion. There was no concretion or foreign body in the appendix, and the inflammatory process began deep in the wall of the latter. Histological study showed the earliest stage of hematogenous infection. The first changes appeared in the mucous and submucous layers, but chiefly in the lymphoid follicles of the latter. Small foci of polynuclear cells surrounded the minute capillaries, and every stage of inflammation was present, to the extent of complete destruction of normal tissue. The phagocytes contained diplococci in various stages of destruction.

It is pointed out that the experimental lesion elects the same portion of the appendix that is so frequently the seat of stricture in man. In one of the animals inoculated there occurred an early peritonitis with living diplococci in the peritoneal fluid, although there was no perforation. Poynton and Paine suggest that the association of arthritis, mucous diarrhea, and appendicitis has an important bearing upon the problem of autointoxication in the etiology of arthritis in human beings. This association would seem to indicate that rather than arthritis being the primary factor, all the lesions may be the result of the primary cause circulating in the blood. The diplococcus may not be the only offending agent. At any rate these investigations show that the very frequent association of rheumatism and appendicitis may be more than a mere coincidence.

Viability of Hookworm Eggs.

In the summer of 1910 Drs. Charles W. Stiles and Harry M. Miller of the Public Health and Marine Hospital Service began a series of experiments to test the viability of eggs of hookworms and of eelworms in feces allowed to decompose in water. Experiments in the same direction had been undertaken by Stiles and Gardner and reported on. From these experiments and from previous ones by the same investigators, it was found that in fecal material kept in water for 68, 117, 144, 317, 333, 349, 357, and 388 days, all the hookworm eggs identified were dead. The longest period of time after which the experimenters have thus far been able to find hookworm eggs under the conditions described has been 70 days. The longest period after which thus far they have been able to find live eelworm eggs under the conditions described have been 117 to 121 days. It seems, therefore, fairly well established that fermentation for four months kills all the hookworm eggs and that fermentation for three months, as suggested by Stiles and Gardner, will kill nearly if not quite all.

The Modern Treatment of Nephritic Colic.

Surgery, either operative or instrumental, is gradually appropriating to itself the treatment of most diseases, internal or external, barring only the epidemic affections of infective origin. In *La Clinique* of September 1, 1911, Georges Luys urges catheterization of the ureter in cases of the engagement of a renal calculus in this canal. The treatment of this condition hitherto has been almost wholly medical—chiefly administration of anodynes and a resort to the hot bath and other means to induce relaxation. Such treatment, Luys says, is vague and empirical and utterly unjustifiable in view of the powerful therapeutic measures now at our command. He insists that catheterization of the ureter through which the stone is passing should be employed methodically as a part of the treatment of nephritic colic. Why leave nature to do its work badly instead of assisting her in her effort? The calculus tends to descend through the ureter, so why not facilitate its migration, the more so that very often a calculus with rough edges may be retained for a long time inside the ureter, giving rise often to serious complications? Consequently, Luys recommends the passage of a cathether into the ureter as the routine treatment of nephritic colic, and he cites an example of a patient suffering from this complaint treated thus by him with complete success.

News of the Week.

Health of the Canal Zone.—The report of Colonel Gorgas for the month of September states that the total number of deaths from all causes among employees was 57; from disease, 42, and from violence 15, giving the annual average per thousand of 10.63 and 3.80, respectively. Among employees for the month of September of each year the annual average death rate per thousand was as follows:

1904	14.31	1908	12.78
1905	32.00	1909	12.76
1906	57.34	1910	11.47
1907	28.63	1911	14.43

The annual average death rate per thousand in the cities of Panama, Colon, and the Canal Zone, including both employees and civil population, for the month of September of each year, was as follows:

1905	52.31	1909	19.01
1906	54.54	1910	21.60
1907	32.93	1911	21.56
1908	24.91		

In segregating according to race, the annual average death rate per thousand from disease among employees was: For whites, 5.95, and for blacks, 12.24, giving a general average for disease of 10.63. For the same month during 1909 the annual average death rate per thousand from disease among whites was 11.95, and blacks, 8.25, giving a general average of 9.08; and in 1910 from disease among whites, 3.58, and blacks, 0.46, giving a general average of 7.89. Among employees during the month, the deaths from the principal diseases were as follows: Chronic nephritis, 4; [illegible]ntery, clinical, 1; hemoglobinuric fever, 3; [illegible] neumonia, 14; tuberculosis, 5; typhoid [illegible]ver, 1; leaving 14 deaths from all other diseases [illegible]s from external violence. No cases of yellow fever, smallpox, or plague originated on or were brought to the Isthmus during the month.

The Mortality in New York City during the week ending November 11 was 13.30 per 1,000 of the population, a decrease of 1.13 of a point compared with the corresponding week of November, 1910. The mortality from diphtheria and croup for the past week was lower than for any other week in the month of November in the history of the city, there being only 12 deaths reported as against 30 for the corresponding week of last year. The mortality from typhoid fever was 50 per cent. lower, the diarrheal diseases showed a decrease of about 33 per cent., the mortality from pneumonia was 12 per cent. lower, and that of tuberculosis 15 per cent. lower. Two groups of diseases showed an increase, viz., the circulatory and the digestive, these two groups being typified by the heart and liver diseases.

Army Medical Corps Examinations.—The Surgeon-General of the Army announces that preliminary examinations for the appointment of first lieutenants in the Army Medical Corps will be held on January 15, 1912, at points to be hereafter designated. The essential requirements are that the applicant shall be a citizen of the United States, shall be between 22 and 30 years of age, a graduate of a medical school legally authorized to confer the degree of doctor of medicine, shall be of good moral character and habits, and shall have had at least one year's hospital training as an interne after graduation. The examinations will be held concurrently throughout the country at points where boards can be convened. Due consideration will be given to localities from which applications are received in order to lessen the traveling expenses of applicants as much as possible. The examination in subjects of general education (mathmatics, geography, history, general literature, and Latin) may be omitted in the case of applicants holding diplomas from reputable literary or scientific colleges, normal schools, or high schools, or of graduates of medical schools which require an entrance examination satisfactory to the faculty of the Army Medical School. Applications must be complete and in possession of the Adjutant-General at least three weeks before the date of examination. There are at present sixty-four vacancies in the Medical Corps of the Army. Full information can be procured upon application to The Surgeon-General, U. S. Army, Washington, D. C.

The State Civil Service Commission will hold examinations on December 9, 1911, for the following positions: Bacteriologist, under Health Officer, Port of New York, $1,200; Physical Instructor, women only, $45 per month and maintenance. Application blanks must be filed on or before December 1, 1911. For detailed circular and application blank address State Civil Service Commission, Albany, N. Y.

A Ten-Mile Endurance Test for Naval Officers.—Beginning with the new year, every officer of the U. S. Navy, whether afloat or ashore, will be obliged to take a ten-mile walk once a month to prove his fitness for continued service. The walk must be completed within four consecutive hours. Before taking the first monthly walk in each year the officers will be examined by a medical board who will determine whether or not they may take the exercise without danger. If the officer is physically fit he will start on the walk and within three hours, if practicable, after the walk is completed the same medical board will again examine him to determine what effect the exercise has had. Officers serving in the tropics will be obliged to take a walk of only six and two-third miles instead of ten. Any officer who is found by the medical board to be unfit to take the walk or who fails to complete the ten miles, for physical reasons, will be ordered before a retiring board.

A Medical Lord Mayor.—Sir Thomas Boor Crosby, M.D., was inaugurated Lord Mayor of London on November 9. His term will be the 723d Mayoralty of the city, and, as he is 81 years of age, he is one of the oldest, if not the oldest, citizen ever to occupy the office. He is also the first medical man honored in this way. He was knighted in 1907. He is a Fellow of the Royal College of Surgeons and ex-President of the Hunterian Society. At one time he was Demonstrator in Anatomy and House Surgeon at St. Thomas's Hospital.

The Harvey Society Lecture.—The fifth lecture in the seventh course of the Harvey Society lectures will be given by Prof. W. T. Sedgwick of the Massachusetts Institute of Technology on November 25 at 8.30 at the New York Academy of Medicine. His subject will be "Illuminating Gas and the Public Health."

Red Cross Christmas Seals.—The State Charity Aid Association, which has taken charge of the sale of Red Cross Christmas seals in New York State, has appealed to the school principals in five hundred villages to assist by organizing local committees to sell stamps. The sales of the stamps in New York State, outside of New York City, amounted last year to about $32,000. It is hoped that by interesting the schools this amount may be trebled this year.

Prizes of the College of Physicians and Surgeons.—Notice is given that an Alumni Prize of $500 will be awarded at Commencement, 1912, for the best essay on any medical subject, written by an alumnus of the college, and embodying the results of original investigations made by the writer. The essay must be submitted, typewritten, to the secretary of the Alumni Association on or before April 1, 1912. The Cartwright Prize, the requirements of which are the same as those of the Alumni Prize, excepting that it is open to universal competition, will be awarded in 1913.

Railroad Fatalities.—According to the report of the Inter-state Commerce Commission for the year ended June 30, 1911, there were 10,396 persons killed on the railroads of the United States, and 150,159 injured. Of the number killed only 386 were passengers and more than one-half the total number were trespassing upon railroad tracks or stealing rides.

Street Accidents.—The National Highways Protective Society reports that 89 people have been killed and 855 others seriously injured in automobile accidents in the streets of the Greater City of New York since January 1. Of the 89 fatalities 35 were children, and 207 of those injured were children. Col. Edward S. Cornell, Secretary of the National Highways Protective Society, in criticising the carelessness of those operating automobiles also scores hospital ambulances for tearing through the streets at a speed far too high for safety.

Montefiore Home.—At the twenty-seventh annual meeting of the directors of this institution, which was held on November 4, it was announced that the new home would be completed in about eighteen months. It occupies four city blocks, and

provides room for 480 patients. The report asks for $500,000 which was needed to free the home from indebtedness. During the past year, 1,109 patients were cared for in the home and the country sanatorium.

Gifts to Charity.—At the annual meeting of the Hospital for Deformities and Joint Diseases it was announced that Alfred Heinsheimer had given $15,000 for the purchase of two houses in East 123d street, adjoining the rear of the present two houses of the hospital. Mr. Heinshimer also gave $10,000 for the maintenance of a room. Two other gifts of $500 each were also announced. The will of James C. Atwater leaves $3,000 to the Brooklyn Homeopathic Hospital. Mrs. Francis D. Colburn has given $500 to the hospital of Milford, Mass. The will of the late Benjamin F. Stanley leaves the Anna Jaques Hospital of Newburyport, Mass., $500, and the same amount to the Homeopathic Hospital.

The Robert Dawson Memorial Hospital, which has been erected at a cost of $125,000, will be ready for occupancy on January 1. It is situated on land adjacent to the Boston University Medical School and connects with the Massachusetts Homeopathic Hospital. This hospital was erected for the purpose of clinical research and for the furtherance of preventive medicine.

A Hospital for Walla Walla.—The Sisters of Charity of the House of Providence are about to erect a $200,000 hospital for this city. This organization has just completed a hospital at Vancouver and operates a majority of the Roman Catholic hospitals on the Pacific Coast.

Sellers of Bad Food Convicted.—Sixty-five offenders against the pure food laws were recently arraigned in the Court of Special Sessions last week and practically all of those tried were convicted of selling adulterated or unwholesome foodstuffs and were fined.

Antivaccinationist Sues.—Herbert A. Thorpe, a resident of Staten Island, has brought suit against the Board of Education of New York City for $10,000 damages for attempting to compel his two children to be vaccinated. Some time ago Thorpe was summoned to the police court for violating the compulsory education law but no charge was entertained against him on his representation of his antivaccination principles. The case will be heard before the Supreme Court sitting in Richmond.

Dr. Robert E. Coughlin has been appointed Chairman of the Medical Association of the Greater City of New York, for the Borough of Brooklyn, in placed of Dr. J. Scott Wood, resigned.

Prof. Wilhelm Wein of Würzburg University has received the Nobel prize for physics.

Canadian Census.—The population of Canada is announced as about 7,150,000, according to the last census, instead of the eight millions for which its loyal inhabitants were wishing. The increase in the last decade was less than two millions.

The Burke Foundation.—The appraisal of the estate of the late John M. Burke of New York shows that over two million dollars will be available for the Winifred Masterson Burke Relief Foundation, which is designed to aid and help the worthy poor who shall have been ill, especially during convalescence from serious illness. The Servants of Relief for Incurable Cancer receive a bequest of $2,500.

Deutsches Zentralkomitee für ärztliche Studienreisen.—The general secretary of the committee, Herr Dr. A. Oliven of Berlin, sailed in the steamship *Cleveland* for New York on October 3, for the purpose of making arrangements for the medical students' tour of America next year, in connection with the International Congress of Hygiene in Washington in October, 1911.

For Purer Candy.—As the result of a conference between Dr. Wiley and the dairy and food officials of Pennsylvania, it is probable that the manufacturers of confectionery will be required to change the coating on some of their Easter novelties and candies. Much of this coating has been condemned as varnish, while the coloring is said to be due to iron rather than chocolate. As two-thirds of the country's supply of these goods is produced in Pennsylvania, there is general interest in the action there.

Appropriation for Health Work.—The Budget Committee of the Board of Estimate of this city has increased the allowance for the Board of Health by over half a million dollars, an increase of 20 per cent. over the budget of 1911. A large proportion of this is for the work among school children and among tenement mothers and children. The examination of school children now confined to the public schools is extended to parochial schools and the corporate and other free schools. The largest increase is for milk depots. The Health Department estimates that the experiments in this regard the last year saved 16,000 infant lives, and it is now proposed to put this work on an all-year basis. Forty additional milk stations are to be established next year, and for this purpose $126,000 additional is provided, making a total of $165,655 for milk depots in 1912. It is proposed to increase the total allowance for other work in the Division of Child Hygiene from $344,340 to $459,990.

Protest Against Quarantine.—Gen. J. Franklin Bell, commander of the Department of the Philippines, has lodged a protest against the health officials of San Francisco who quarantine United States Army transports bringing troops from Manila for several days, sometimes as many as five, whereas merchant vessels from Manila are usually released at the end of twenty-four hours. The quarantine authorities allege as the cause for discrimination against army vessels that the soldiers are gathered from all over the Philippines, while the other steamers usually carry passengers picked up principally from Manila.

The Pure Food Law in Louisiana.—At a meeting of the Louisiana State Board of Health in October a resolution was passed making the pure food laws of that State uniform with those of the United States Government, except in cases where the government laws might conflict with those of the State Legislature.

Against a State Grant to a Medical School.—The Illinois State Homeopathic Society has brought suit against the State Auditor to restrain him from paying to the University of Illinois $60,000 appropriated by the last assembly for the maintenance of the school of medicine of that institution located in Chicago.

College Assessment for Medical Attendance.—The students at the Kansas Agricultural College in Manhattan, Kan., have entered into an arrangement whereby by the payment of 50 cents a term, or $1.50 a year, they will be entitled to the services of a physician and of a visiting nurse when ill.

A Fee Bill.—The Montgomery County, Ill., Medical Society has adopted a new fee bill as fol-

lows: Office fee, minimum $1. Day visits in city, $1.50; night in city, $2; day visits in country, $1.50 plus 50 cents a mile; at night in country, $2 plus 75 cents a mile; consultation fee, minimum (with mileage above), $5; obstetrical cases (uncomplicated) with mileage as above, $15; same with instruments $25; surgical cases requiring anesthetics, $10 and up; administering anesthetics, minimum, $5; insurance examinations (not fraternal), minimum, $5; visits to contagious diseases, mileage extra, $5.

County Medical Society Sued.—Dr. Louis Anton Ewald has brought suit against the Medical Society of the County of New York to compel the society to amend its records to show that he resigned last December and consequently could not have been expelled in April.

The Medical Society of the State of Virginia at its annual meeting held in Richmond, October 24 to 27, elected the following officers: *President,* Dr. Hugh M. Taylor, Richmond; *Vice-Presidents,* Drs. Samuel Lile of Richmond, Joseph Grice of Portsmouth, and S. B. Moore of Alexandria; *Secretary,* Dr. Paulus A. Irving, Farmville; *Treasurer,* Dr. Grear Baughman, Richmond.

Obituary Notes.—Dr. John Lombard Dale of Springfield, Mass., a graduate of the University of Pennsylvania, Department of Medicine, in 1872, died October 30 in his sixty-second year.

Dr. John Bunton Palmer died at his home in this city on October 30. He was a graduate of the New York Homeopathic College in 1892 and was professor of diseases of the nose and throat at the New York Medical College and Hospital for Women and attending laryngologist to the New York Ophthalmic Hospital.

Dr. Israel G. Heilman died of heart disease at Philadelphia on October 26, at the age of 65 years. He was graduated from the medical department of the University of Pennsylvania in the class of 1873.

Dr. C. B. Bates, for many years a practising physician of Santa Barbara, Cal., died at his home in Nahant, Mass., on October 13. He was born in England in 1842 and went to California in 1862. He studied medicine at the California State University and in Philadelphia, and practised in Santa Barbara from 1869 until about nine years ago, when he moved to Boston.

Dr. William N. Swift, a graduate of the Medical School of Harvard University, Boston, in 1881, died at his home in New Bedford, Mass., after an illness of several weeks, aged 58. He was a member of the American Medical Association.

Dr. Edward D. Hooker, a graduate of the Medical School of Harvard University, Boston, in 1884, died at his home in Arlington, Mass., October 31. He was a member of the American Medical Association.

Dr. Lewis E. Morgan, a graduate of the Medical School of Harvard University, Boston, a practising physician in Cambridge for many years, died at his home in Hanover, Mass., October 27, aged 48. He was a member of the American Medical Association.

Dr. Samuel McCurdy, a graduate of the Cooper Medical College, San Francisco, Cal., in 1872, died October 25, in Berkeley, Cal., aged 64.

Dr. Josephine Griffith Davis, a graduate of the Woman's Medical College of Pennsylvania in 1877, died at her home in East Orange, N. J., November 8, aged 72.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

THE "GAG" OF THE BILL—SLEEPING SICKNESS—SARCOMA OF TIBIA—THYROID MALIGNANCY—LEAGUE OF MERCY—ELECTION TO GENERAL MEDICAL COUNCIL—OBITUARY.

London, October 27, 1911.

Parliament has resumed after its recess, and the Government has determined to force the insurance bill through by means of the "gag," or, as it is also called, the guillotine. The premier says this is necessary in order to make it an act before Christmas. With curious logic, there scarcely being time even with the gag, he mentions half a dozen other measures which he is determined shall pass. The chancellor pretends that his conferences during the recess have satisfied the interests involved. If so, I still hear objurgations from friendly societies. Then the doctors cannot be said to have accepted the bill until the meeting I told you of has taken place, and the British Medical Association has not withdrawn its demands, although some fear that their leaders are weakening. They can scarcely venture to give way on the wage limit, however, angry as the societies may be, and they must insist on this limit being inserted in the bill. Mr. Lloyd George should be made to understand that the profession will make no arrangements with his insurance authorities to attend people with more than £2 weekly income. This and two other points have been accepted by the House of Common as reasonable, and that by a large majority. The Government should be plainly told that any further trifling with these and the profession will refuse to have any more to do with his scheme. A strong party would welcome this result, which would end the contract system, and that party considers the opportunity of doing so might have been seized at the outset. They would be supported now by those politicians who denounce the gag in a more extended way than ever as being introduced to form a precedent for still more autocratic encroachments on parliamentary discussion.

Another commission on sleeping sickness is shortly to leave for central Africa, under the auspices of the Royal Society and the British Government. Col. Sir D. Bruce will be in charge and Lady Bruce goes with him. Captain Hamerton, R.A.M.C.; Professor Newstead of the Liverpool tropical school, Major Harvey, R.A.M.C.; Staff-Sergeant Gibbons, and Mr. James Wilson, are the other members. The work will be confined to Nyassaland, where forty cases have been reported since 1909, and the question whether in that country the carrier of the disease is other than the tsetse will be one of the first for investigation. It has been very positively asserted that the *Glossina palpalis* is not met with in Nyassaland, and therefore suggested that the parasite may not be the same which causes the disease in other parts of Africa. The commission will also examine what proof there may be in the suggestion that sleeping sickness in Nyassaland is due to the presence of big game, or any wild animals. It is certain that several species of tsetse can convey trypanosomes to domestic animals. In Uganda sleeping sickness has been most studied and definitely traced to the *Trypanosoma gambiense*, but in Nyassaland it has some difference, and has been termed *rhodesiense*. The difference, however, is

not very great, and one observer speaks of it as a mere "freak." These parasites are not rare in some countries. Dr. Chagas found trypanosomes exceedingly common in Brazil. One form, he said, could be found in most of the infants there during their first year. Many, it seems, succumb to the infection, but the others become immune. It has been reported that the parasites have been detected in fishes in the Norfolk Broads and in calves in England.

Sir David Bruce's commission may be expected to settle many of the questions suggested by the varying statements which have been made. His first attention will be directed to decide whether the *T. rhodesiense* frequently exists in the lower vertebrates as well as in man. Then whether the animal sickness (nugana fever) can be communicated by *Glossina palpalis,* as well as by the *G. morsitans.* You will remember that on some small islands in Uganda lakes Professor Minchin reported there were swarms of tsetses where no game and no human beings were within their reach, and they seemed to live on the blood of birds. Perhaps they are less dainty than has been supposed.

At the opening meeting of the R. S. M. Sir F. Eve showed in the clinical section a case of myeloid sarcoma of the tibia of six months' duration in a girl of eighteen. The diagnosis was confirmed at operation, which was then further proceeded with. The upper third of the tibia, containing the tumor, was resected, and the articular cartilage of the femur also removed. Then six inches of the fibula were sawn off, carefully preserving the periosteum. A hole was bored into the end of the femur and another into the tibia, and the piece of fibula bolted into these holes, the ends of the two bones being separated for 1¾ inches. Primary union followed, radiographs taken from time to time showing that new formation of subperiosteal bone increased the size of the transplanted fibula and the interval between the femur and tibia diminishing. It was mentioned that experiments lately made by Axhausen and Lobenhoffer showed that when transplanted bone is covered with periosteum the osteal substance dies, but periosteum and endosteum live. Hence, in operations where fixation of graft is required the periosteum must be carefully preserved. It was remarked, too, that myeloid sarcoma does not recur after local removal. Sir F. Eve said he had seen within the week two cases showing this, one eighteen years, and the other four and a half years after operation.

Mr. Elmslie showed a case of general thyroid malignancy in a woman of sixty-one. Pain in the wrist, treated at first as rheumatic, was followed by swelling which a skiagram showed to be endosteal of the lower part of the shaft of the radius. Suspected to be sarcoma, a portion was excised last July, but it was found to be composed of thyroid tissue, not evidently carcinomtaous, but resembling an adenoma of the fetal type of thyroid. Later the left lobe of the thyroid was found large and hard, but not fixed, though the patient said it had been so for years. The veins on the left side of the neck had become distended; movements of the vocal cords were unaffected. The whole skeleton had been examined by skiagraphy, but no other bony tumor discovered.

The grants made by the League of Mercy to extra-metropolitan hospitals for 1911 amount to £2,200, making a total of £9,861 given to hospitals outside London in counties which called for the league. To King Edward's Fund for the London hospitals the league has contributed since its origin £153,000. At a meeting in support of the league on Tuesday Sir J. Crichton-Browne affirmed it would be a national calamity if the Government took over the hospitals, for it would certainly withdraw them from the all-pervading intimate interest which vitalizes them, make their organization rigid instead of plastic, and impair their usefulness as centers of medical science and teaching. The insurance bill, too, he felt, unless greatly modified, would cripple the hospitals. Mr. Lloyd George admitted it would cause temporary irritation. The risk was that it would induce permanent hardness of heart. Mr. George professed supreme faith in the goodness of human nature. But there would come to many a time when it was necessary to reduce expenditure, for honesty required a man to pay his way before indulging in charity.

Electioneering *re* the General Medical Council is already going on. Two members whose terms expire next month are candidates again, and one as the first additional representative which has been granted. The British Medical Association is, as usual, first in the field, and its ruling clique is urging in the name of the association the election of their three nominees, and that not only in the journal, but through the branches and by circulars. Discontent is natural, for we are not satisfied to commit every movement to the control of a body of which the previous record is not creditable. There are three other candidates to oppose the three whose only disqualification is that they are nominees of the British Medical Association. If this association is always to monopolize the representation the election will become a farce.

In the death by "suicide during temporary insanity" of Dr. A. P. Hillier, M.P., the profession loses an able representative in Parliament, although he had retired from practice. Born in 1858, he served with the colonial forces in the Kaffir war of 1878-9, and was a member of the Johannesburg Reform Committee in 1895-6. He had taken B.A. at the Cape University in 1877. In 1882 he took M.B. Edin., and proceeded to M.D. in 1884. He became a member of the Association for the Prevention of Tuberculosis, displayed great interest in the open-air treatment, was a consultant of a sanatorium, and held other important offices, including the presidency of the South African Medical Congress (1893), and was a delegate to the Berlin Tuberculosis Congress, 1899. He wrote "South African Studies," "The Commonwealth," "Tuberculosis: Its Nature, Prevention, and Treatment," and other works, as well as journal articles, and for a time edited *Tuberculosis.* In January, last year, he was elected M. P. for Hitchin, and has been working hard ever since, both in politics and otherwise. At the inquest yesterday, when the verdict cited above was found, it was shown that he had no troubles, either financial or domestic. He rather worried about the illness of his son in India and was the subject of some heart disease which had interfered with sleep lately, but had never shown any delusion until just before the sudden attack which proved so fatal. It is evidently one of those cases of sudden breakdown in very active persons who have been overworking. His brother stated that he did the work of two men.

Dr. John Breakey, R.N., inspector-general of hospitals and fleets (retired), died on the 21st of

October. He became surgeon in the navy in 1854, staff surgeon in 1863, fleet surgeon in 1876 and inspector-general in 1886, retiring in 1889. He served in the Baltic during the Russian war, 1854, and was present at the bombardment of Bomarsund. In the China war of 1857-8 he also served and was awarded both the China and Baltic medals.

Col. Michael Cogan, R.A.M.C. (retired) has died at the age of seventy-one. He qualified at the two royal colleges in Dublin, 1862-3, and joined the army medical service the following year. He was in the Afghan war of 1878-80, for which he held the medal. He retired in 1897.

The death is reported by cable of Surgeon-Major Campbell Dykes of the Indian Medical Service. He took the double qualification and M.B. Lond., in 1897, and entered the service in 1899, reaching the rank of surgeon-major last January.

Dr. Stanley Smith, physician to the Railway Fund, etc., died on the 25th of October, after a short illness, aged fifty-nine. He qualified in 1877 at the London College of Surgeons, and added Edinburgh, 1882. In 1895 he joined the College of Physicians in London and took M.D. Durham.

Dr. George Thorn, J.P., consulting surgeon to the Royal Albert Hospital, Devonport, died there on the 8th of October after a few hours' illness. He was sixty-six years old and had been a magistrate for many years.

OUR LETTER FROM PARIS.

(From Our Regular Correspondent.)

PYORRHEA ALVEOLARIS, ORIGIN, AND LOCAL AND GENERAL CONSEQUENCES—LOCAL TREATMENT OF SYPHILIDES OF THE TONGUE—DIFFERENT SORTS OF PSYCHOPATHIC PAINS, THEIR SIGNIFICATION AND THEIR ROLE—TUMORS OF THE PITUITARY BODY—VALUE OF THE TESTIMONY OF THE INSANE IN COURTS OF JUSTICE—DEATHS OF PROFESSOR DIEULAFOY AND PROFESSOR CHARPY.

PARIS, Sept. 20, 1911.

THE second French Congress of Stomatology was opened during the early days of August at the Faculté de Médecine, Paris, with Professor Landouzy as president. The question which was the order of the day was pyorrhea alveolaris, its origin and local and general consequences. Tellier of Lyon presented the paper. The author defined the pyorrheic state as a chronic pathological state characterized by the progressive destruction of the fixing tissues of the teeth and the almost constant appearance of suppuration, due to constitutional or local causes, lessening of the resistance of the tissues and favoring the local affection. This results in the falling out of the teeth and may be accompanied or followed by general complications.

The local treatment of syphilides of the tongue was considered by Hallopeau. The author believes that with 606 or hectine we can positively arrest syphilis in its evolution; but we should not at the same time neglect local treatment, for the multiple functions of the tongue aggravate the specific lesions in this situation. We can cause the ulcerations and mucous patches to disappear by touching with acid nitrate of mercury. But if the lesions are extensive it is desirable to transform the buccal cavity into an antisyphilitic medium by the frequent sucking of pastiles containing a milligram of corrosive sublimate or a centigram of hectine.

The second congress of alienists and neurologists opened at Amiens on August 1, under the presidency of Deny of Paris. Three subjects were submitted to the members of the congress. The first was the different kinds of psychopathic pain, their significance and their rôle. Maillard distinguishes four groups of psychopathic pains; hallucinatory pains, due to hallucinations; hysterical pains, due to autosuggestion; paranoiac pains, determined essentially by delirious interpretations, and cenesthopathic pains, which consist in abnormal painful sensations of which the persistent duration affects the patient. Picqué of Paris endeavored to state what should be the conduct of the surgeon in the presence of these pains. When there exists an important lesion, such as a cancer or tumor, the surgeon should operate; but if the surgeon does not find any such lesion he should abstain from interference. The second question was tumors of the pituitary body. Cortellemont of Amiens read a paper. Primary tumors of the pituitary body are important and relatively frequent. From the size of a nut to a cherry they may attain the size of a hen's egg or a mandarin; these tumors are for the most part glandular. The symptoms determined by tumors of the pituitary body are first mechanical, those of cerebral compression: headache, vomiting, vertigo, nervous depression, and especially ocular troubles. The dystrophic states determined by tumors of the pituitary body are the deformities of acromegaly or gigantism, hypophyseal adiposity, or genital dystrophy. The diagnosis should be very reserved; it should be positive only when the clinical picture is complete. As treatment opotherapy appears to be only symptomatic; on the contrary, radiotherapy appears to have given functional and physical results that are very acceptable. Sainton of Paris insisted on the especial characteristics which glycosuria takes on in tumors of the pituitary body. The sugar content is very high; it is accompanied by symptoms of true glycosuria. The third question was the value of the testimony of insane persons in a court of justice, by Lalanne. All psychopaths are capable of being mistaken or of lying; the dements make false statements on account of failure of memory and attention; maniacs by malevolence; melancholics by ideas of culpability; the persecuted by the hope of vengeance or defense; the intoxicated by oneirism; the hysterics by mythomania; the epileptics by lacunæ or absences. All the testimony of the insane should be subject to careful examination.

The next congress of alienists and neurologists will be held at Tunis in 1912, president M. Mabille. The principal questions are psychoses of paludism, instinctive perversions, and assistance for colonies of the insane.

Professor Georges Dieulafoy, of world-wide renown, has died prematurely. Among great contemporary physicians Dieulafoy was remarkable above all for his brilliant qualities as professor and educator. His professional probity, his scruples in regard to the duties of the physician, the respect in which he was held by his patients, the additions he made to medical achievement, the devoted affection which he gave to his pupils attracted the admiration of all who knew Dieulafoy. He was a marvelous professor of internal pathology; all medical questions, even the most arduous, he made accessible and attractive to all. He was the author of that famous "Manual of Internal Pathology" which from its first appearance went through sixteen editions, which in France instructed several generations and carried abroad the renown of French clinical medicine. Dieulafoy was the favorite pupil of Trusseau and

his teaching clearly reechoed that of his master. One could not say what was to be admired most: his alert and vigorous style and clinical acumen or his marvelous eloquence. The great amphitheater of the Hôtel-Dieu, where he lectured so long on clinical medicine, was always too small to hold the crowd of his admirers. With Dieulafoy disappeared one of the most eminent masters of French medical science.

Charpy of Toulouse has also died prematurely. He was one of the celebrities of French medical science. He studied at the Medical Faculty of Lyons. Later he was made professor of anatomy at the Medical School of Toulouse, where he remained a long time. The character of his teaching was simple, clear, luminous, illustrated with many careful figures and schemata. His two volumes on the "Anatomy of the Central Nervous System" and the "Anatomy of the Genitourinary Organs" are a revelation of his brilliant qualities as a professor and savant. Later he published with the late Professor Poirier the "Treatise on Human Anatomy." Recently there appeared the résumé of the work under the name of "Anatomy Abridged." Death seized him at the moment when he was working on a third edition of the "Treatise on Anatomy."

COLORED PHOTOMICROGRAPHS.

To the Editor of the Medical Record:

Sir:—Referring to the article on "Photomicrographs in Natural Colors" appearing in the October 7 number of the Medical Record, I would say that ever since the advent of the Lumière Autochrome plates I have been frequently called upon to produce photomicrographs in their natural colors, and can say from experience that the difficulty of producing positives on glass by this process is not much greater than the production of ordinary lantern slides. When, however, it is desired to reproduce these photomicrographs upon paper in their natural colors the difficulty is somewhat increased, as use must then be made of the three-color process. However, a little experience will soon enable a person familiar with photography to obtain three negatives from the autochrome in their correct color values, and, with these, several methods are then available for their impression upon paper.

Remarks on High Blood Pressure and Arteriosclerosis. J. M. Jackson.
Treatment in Circulatory Disorders. H. D. Arnold.
An Experimental Study of the Cause of Death in Acute Intestinal Obstruction. F. T. Murphy and B. Vincent.

Prevalence of Circulatory Disease.—By E. W. Dwight. (See page 1044.)

The Production of Arterial Blood Pressure.—W. B. Cannon emphasizes the necessity of keeping in mind both the discharge from the heart and the constriction of peripheral vessels as determinants of arterial pressure. A low pressure may be due not to vasodilation but to a weak heart; and any agency used to increase vasoconstricto: tone under these circumstances is likely to stop the heart at once. The author's attention has recently been called to a case of precisely this character, in which the administration of adrenalin to raise the low tension was followed by instant death—the laboring heart was overburdened by the sudden increase of load and stopped immediately. Until the part played by each of the two factors therefore—the heart and the arterioles—is clearly discriminated, the intelligent treatment of any disturbance of normal arterial pressure is impossible.

High Blood-Pressure and Arteriosclerosis.—J. M. Jackson states that the causes of arteriosclerosis may be summed up under the heads: (1) toxic—*e.g.* lead, infections of all sorts, excess of certain internal secretions, such as adrenalin, and absorption from the intestinal tract of certain putrefactive products; (2) senile or quasi-senile, in which would be included the wear and tear from overwork; and (3) heredity.

Treatment of Circulatory Disorders.—H. D. Arnold states that the determination of the blood pressure in many of these cases indicates the general line of treatment. If a relatively weak heart struggles against a high pressure the best drugs to administer are digitalis and strychnine, used cautiously and often in very small doses. When given in this way digitalis does not increase the blood pressure. Nitroglycerine should be used to lower the blood pressure. Rest is of cardinal importance. Hydrotherapy is not useful in this condition, but high-frequency currents are efficient in reducing high blood pressures. The most important factor in the treatment is the proper regulation of the diet. The essential feature of this dietetic treatment is the limitation of the amount of protein in the food.

Cause of Death in Acute Intestinal Obstruction.—F. T. Murphy and B. Vincent conclude that interference with an obstructed intestine is the vital factor in the production of the typical symptoms of acute ileus. The obstruction of the venous return is the most important element in this circulatory disturbance. The acute symptoms are caused by the absorption of a toxic substance which is found in the obstructed intestine. This toxic substance is destroyed by boiling. It is not soluble in water and will not pass through the Berkefeld filter. The formation of this substance probably is not dependent on any vital secretion of the mucous membrane of the intestine. The rapidity of absorption varies, dependent on the patency of the lymphatic channels in the mesentery and the permeability of the intestinal wall. This toxic substance is purely bacterial in origin, and the living bacteria with their endotoxins, and not the putrefactive products nor the chemical poisons, are directly responsible for the profound symptoms and death in acute intestinal obstruction.

Acute Dilatation of the Stomach Following a Herniotomy Done under Local Anesthesia. H. H. M. Lyle.
Tubal Sterilization as a Prophylactic Measure. M. A. Werner
Surgical Measures *versus* Palliation in Epididymitis. F. C. Walsh.

Evolution of the Operating Table.—W. S. Bainbridge discusses this subject and traces the development of the surgical table from the wooden household table of former centuries to the up-to-date enameled adjustable table, in which drainage, universal adaptability, simplicity of mechanism, and the requirements of asepsis are the objects in view. The author has devised a table with a nickel top which will not chill the patient like glass, which will not break like the latter, nor stain like baked enamel, nor chip like porcelain-enameled iron. This table has the following attachments: an anesthetist's screen, foot brakes, side extensions for the arm, leg holders, a perineal instrument

tray, a swinging instrument rack with detachable tray, shoulder supports, a foot-supporting plate, a goiter attachment, and an elevating bridge with hip and heel stirrups.

Heredity and Tuberculosis.—G. B. Sweeny believes that, while tuberculosis is not inherited, nevertheless there is a constitutional tendency to this disease.

Bronzed Diabetes.—By G. Blumer. (See MEDICAL RECORD, July 22, 1911, page 200.)

Postoperative Röntgenization in Cancer.—By C. E. Skinner. (See MEDICAL RECORD, October 21, 1911, page 846.)

Dural Endothelioma.—N. J. Dynan reports a case of this condition occurring in a man aged seventy-two years. The tumor involved the frontal lobes.

Gastric Catarrh.—J. A. Work states that a large percentage of cases of chronic catarrhal gastritis accompany other more general diseases. Gastritis is a definite pathological entity, not a neurosis. A careful examination of the stomach contents will differentiate it from a neurosis. The presence of mucus with incorporated epithelial cells and evidence of diminished secretory activity are valuable points in the diagnosis. Diagnosis in doubtful cases must be reserved until several stomach analyses have been made. In carcinoma the reduction of free acid and of peptic power is an early symptom, while in chronic gastritis it appears late. The marked chronicity of gastritis and the rapid course of cancer are important distinctions. The pain of gastritis is milder and more diffuse than that of ulcer. There is no hematemesis in a pure gastritis, though evidence of minute hemorrhagic erosions may be found in the contents of vomitus. The three most trustworthy points in making a positive diagnosis are microscopic or cytological analysis, reduced zymogen and hydrochloric acid secretion, and abundant formation of mucus.

Acute Gastric Dilatation.—H. H. M. Lyle reports a case of this condition following a herniotomy done under local anesthesia. This case indicates a possible cause of acute dilatation. In all probability the removal of a portion of the omentum profoundly altered the circulation and possibly the nervous mechanism of the stomach, thus causing a temporary muscular paralysis.

Tubal Sterilization.—M. A. Werner notes that the conditions warranting this procedure as a prophylactic measure are the following: tuberculosis, heart disease, marked pelvic contraction, and psychoses in which a tendency to suicide is manifested during pregnancy.

Section of the Epididymis.—F. C. Walsh recommends this procedure as a rapid means of relieving pain, shortening convalescence, preventing recurrence, and decreasing the tendency to sterility, in the treatment of gonorrheal epididymitis.

Streptothricosis of the Lungs.—By N. Bridge. (See MEDICAL RECORD, July 1, 1911, page 47.)

Rickets.—By J. W. Cokenower. (See MEDICAL RECORD, July 8, 1911, page 108.)

Intestinal Parasites.—W. E. Sistrunk states that the common belief that intestinal protozoa are seen only in persons who have lived in or visited the South or tropics is erroneous. They are frequently found in persons who have always lived in the North and, when seen in great numbers, are generally found associated with chronic diarrheas, obscure abdominal pains, or anemias. Many infected cases are probably overlooked; first because parasites are not suspected, and, hence, not looked for; second, because poor technique is used in examining the specimens. Of the animal parasites found in patients who had never been in the South, protozoa were more frequently seen than all the other varieties. *Entameba tetragena*—a pathogenic ameba recently separated from *E. histolytica* and *E. coli* by Viereck—was often found in persons who had never been in the South. It is probable that this organism accounts for many of the chronic diarrheas seen in persons living in this part of the United States.

Management of Failing Circulation.—E. Schmoll divides heart diseases into two groups, one including all of a rheumatic origin and the other characterized by progressive arterial disease. The common signs of failure in the first group are râles at the base of the lung posteriorly, a gain in weight, enlargement of the liver and edema of the ankles. It is in these cases that digitalis deserves its reputation. In those of the second group, though the symptoms may closely resemble those of the first, digitalis will only aggravate the condition. Not only is the heart diseased, but almost every other vital organ is affected by deficient blood-supply, which is especially the case with the kidney. Here a salt-free low-protein diet is indicated, supplemented by free use of diuretics. In studying the physical changes in one organ in all these cases on must not overlook the secondary changes elsewhere.

Cadiac Irregularities and Treatment.—A. W. Hewlett states that each form of irregularity has its own problems. With regard to treatment these have been in part solved, but for the most part they still await solution. To accomplish this there is needed more experimental evidence having direct bearing on the use of drugs in cardiac irregularities, and especially concerning the effect of drugs on the irritability of the heart muscle, for abnormal irritability seems to play an important part in the causation of extrasystoles and auricular fibrillation. Finally, there are needed more accurate studies on the effect of cardiac remedies on patients with heart disease.

Digestive Secretions and Digitalis.—W. Hale has noted that the acid of the gastric secretion invariably causes some diminution in the action of the glucosides of digitalis and strophanthus. The rate of deterioration appears to be about 25 to 35 per cent. in three hours. The action of the decomposition products of these glucosides must be considered, and it is possible that certain of the untoward effects of digitalis medication may be due to them. It would seem advisable, therefore, to prevent such decomposition if possible, and it is suggested that this might be done by requiring the official galenical preparations to be neutral and in practice by prescribing an alkali along with the digitalis. Ignoring the specific irritant action of these bodies on the intestinal tract, it would also seem advisable that the drug should be given between rather than at meals when the gastric acidity is at the maximum. Such a procedure might possibly not cause undue irritation if a large quantity of fluid were taken at the same time.

Treatment of Myocardial Lesions.—W. W. Kerr states that recent researches have suggested that accumulation of lactic acid in the tissues is responsible for a considerable proportion of the cases of myocardial distress. So far as they relate to the heart he suggests that the

muscles of the whole cardiovascular system may be poisoned by a very slight increase in th amount of lactic acid in the tissues. The author speaks favorably of the use of calcium chloride as advised by Lauder Brunton for the purpose of maintaining the heart's action when failure is imminent.

Gastric Ulcer.—W. J. Mallory states that at present the medical treatment of ulcer of the stomach is far from satisfactory. Until the pathogenesis of the condition is made clear and a treatment based on etiology is possible, one's chief hope for better results must rest on earlier diagnosis, and this will be attained when one depends less on objective symptoms and uses more generally the tests for occult blood in the feces.

Dust and Municipal Diseases.—By H. S. Anders. (See MEDICAL RECORD, September 30, 1911, page 699.)

Banti's Symptom-Complex.—J. F. Hultgen states that the diagnosis of Banti's disease rests on the presence of the splenomegaly, the anemia with leukopenia, and the ascites. Any case with hematological findings leaning repeatedly toward leucemia should not be included under splenic anemia. The prognosis of the Banti symptom-complex is fairly good as to life as long as it retains its special character. The therapy should be conservative, though Sutherland and Burghard, as well as Banti, advise splenectomy.

Cardiac Hypertrophy and Myocarditis.—L. Loeb and M. S. Fleisher refer to their method of producing hypertrophic and myocarditic changes in the heart of the rabbit by intravenous injections of adrenalin. They do not think that this drug causes a constriction of the coronary vessels and by this action produces a myocarditis. They also exclude a direct toxic action on the heart and hold to their former theory of mechanical strain with its physicochemical sequels as the true cause. Applying these experiments and theories to certain pathological conditions in man, they find practically the same conditions in many respects in the human heart as in that of rabbits, though there is less prominence of the parenchymatous degenerative changes in the muscle-cells in the rabbit.

Diffuse Septic Peritonitis.—R. S. Fowler presents a review of 194 cases of acute septic peritonitis due to appendicitis. He believes that the ideal treatment, *i.e.* the Fowler position, the keeping of the stomach empty by withholding all nourishment, or if the stomach fills through retroperistalsis, by lavage with siphoning dry of the stomach, and the administration of saline by the Murphy method of proctoclysis, should be carried out in the majority of cases. In addition he suggests that a culture be taken at each operation and a vaccine be immediately prepared and given.

Occult Blood Test.—W. A. Newbold reports a case in which examination of the stools revealed the presence of minute portions of a material that looked like blood but proved to be watermelon pulp. Experiments proved that the coloring matter of watermelon pulp would give the characteristic chemical tests for blood, and the expressed juice of the melon also gave a similar color reaction but less intense. Watermelon is so common an article of food during the heated season that this possible source of error should be considered.

Sciatica.—A. J. Caffrey reports a series of cases illustrating the good effect of deep perineural injections of beta-eucaine in the treatment of sciatica.

Tonsil Hemostat.—A. M. Corwin describes a new instrument of this kind that he has devised.

Immunity.—C. C. Bass presents a new theory of this subject.

Absence of Appendix.—G. F. Shiels reports the case of a young woman in whom a diagnosis had been made of chronic appendicitis with predominance of epigastric symptoms and constipation. At operation there were found numerous adhesions in the region of the cecum. No appendix, however, was present. There was no evidence of inflammatory obliteration of this organ. The author regards the case as one of congenital absence of the appendix.

Fibroid Complicating Pregnancy.—By F. M. Lazard. (See MEDICAL RECORD, July 1, 1911, page 50.)

The Lancet.

Torsion of the Funis as a Cause of Death of Twins. H. A. Lediard.
The Action of the Products of Homogeneous Fetal Autolysis on Malignant Tumors in Man. Preliminary Note. G. Fichera.

Suppurations in Nasal Accessory Sinuses.—H. Tilley states that 6.8 per cent. represents the average of sinus suppuration in the general mass of the population. As regards danger to life antral disease may exist for years and the patient may appear in perfect health. In other cases it may be the cause of gastric disturbances, mental depression, and a host of other symptoms which render life intolerable. Between these extremes are intermediate cases. The antrum is far removed from vital structures. In dealing with the frontal, ethmoidal, or sphenoidal sinuses—or, what is very frequent, a combination of these sinuses in a state of suppuration—the mere fact of chronic suppuration being present in one of these sinuses in a patient whose general health is good, in whom there are no local symptoms of importance beyond a slight discharge of pus or muco-pus from the nose, does not warrant the surgeon in advising radical operations until simpler measures have been tried and there are cogent reasons for passing to severer ones.

Treatment of Diabetes Mellitus.—E. I. Spriggs discusses the dietetic treatment of this disease when diacetic acid is not present in the urine.

Post-Nasal Catarrh in Children.—Eustace Smith states that of late years he has been in the habit of examining the fauces of all children who have been brought to him suffering from loss of appetite, gastric derangements, spasmodic conditions of the air-tubes, and obstinate coughs. In a very large number of these cases he has found the patient to be suffering from a more or less intense post-nasal catarrh. This catarrh is often confined strictly to the nasopharynx, and does not pass into the nasal passages. While thus limited it may give rise to none of the usual signs of "a cold" in the nose, such as snuffling, sneezing, and external discharge, or even to a throaty quality in the voice. It may therefore remain latent and escape notice for weeks, or even months, together unless the throat be inspected in a good light. Complete loss of appetite is one of the commonest consequences of persistent post-nasal catarrh. Active disturbances of the stomach, laryngismus stridulus, otitis, cervical adenitis, and general infections such as meningitis may all be secondary to post-nasal catarrh. The treatment of this condition consists chiefly in the use of local antiseptic and astringent applications by means of a throat-brush.

Experimental Appendicitis and Rheumatism.—By F. J. Poynton and A. Paine. (See page 1031.)

The Etiology of Scarlet Fever.—R. W. C. Pierce reports a series of cases which he believes tend to confirm his opinion that a fair proportion of the patients admitted into hospitals as suffering from scarlet fever, although presenting signs which are indistinguishable from those of true scarlet fever, have not in fact necessarily contracted the infection from a previous case of the disease.

Torsion of the Umbilical Cord.—H. A. Lediard reports the case of twin stillborn fetuses, in which he attributes the death of both to torsion of the cord in one.

Products of Fetal Autolysis and Cancer.—G. Fichera based his investigations upon the following facts: Spontaneous malignant tumors are extremely rare in young rats. By previous injections of embryonic tissues rats acquire a marked resistance to the inoculation of neoplasms Homogeneous embryonic or fetal tissues, when subjected to autolysis, by hypodermic injection or by local application bring about the involution of the inoculated neoplastic elements, which always reproduce themselves and prove fatal. This fact strengthens a belief in the existence of substances which are generated by the special tissues during the process of autolysis, which when injected into the organism act on tumors in a way similar to that brought about by the preventive injection of embryonic or fetal emulsion. The author, acting upon these principles, injected into human beings affected with cancer definite and repeated doses of homogeneous fetal autolysates. Of 18 cases in which the treatment was carried out with regularity there were 10 in which the beneficial effects were evident. Three of these cases were cancer of the breast with multiple metastases, one was a cancer of the lower end of the rectum, and one was an adenocarcinoma of the thyroid. The process of involution, studied by successive microscopic examinations, was a diffuse cytolysis of the neoplastic cells, with pronounced phagocytosis and connective tissue infiltration, and with final transformation of the tumor substance into adult connective tissue.

British Medical Journal.

October 28, 1911.

Medical Education, Past and Present. R. Saundby.
Certain Clinically Obscure Malignant Tumors of the Nasopharyngeal Wall. W. Trotter.
Deviations of the Nasal Septum and the Submucous Resection Operation. Records of One Hundred Cases. J. W. Wood.
A Case of Tonsillar Calculus. J. M. McCarthy.
The Treatment of Pulmonary Tuberculosis by Inducing an Artificial Pneumothorax. H. Rhodes.
A Note Upon the Mechanical Effects of a Massive Left-sided Pleural Effusion. N. C. Rutherford.
Creatin and Creatinin in Animal Metabolism. W. H. Thompson and T. A. Wallace.

Medical Education.—R. Saundby reviews the developments in medical education during the past generation. He notes among the modern tendencies too much teaching and too little thinking; the student's time is so monopolized by classes that he has insufficient time and perhaps insufficient stimulus to work things out for himself, for the latter is a most important part of every educational process if the result is to be more permanent than the passing of examinations. Medical education has become less homogeneous, and is broken up into compartments in which the student perhaps attends too exclusively to the subjects in which he will shortly be examined, and regards each examination as an end in itself without recognizing its relation to his profession.

Malignant Growths of Nasopharyngeal Wall.—W. Trotter classifies these as follows: (1) Teratoma. (2) Tumors originating in lymphoid tissue: lymphosarcoma, myxoma, myxosarcoma. (3) Periosteal growths: nasopharyngeal fibroma and fibrosarcoma. (4) Sarcoma of the pharyngeal well: homogeneous forms; round cell, spindle cell, etc.; alveolar, endothelioma. (5) Carcinoma of mucous membrane: squamous, columnar. The author discusses the anatomical considerations in connection with these tumors, and the subjects of diagnosis, prognosis, and treatment.

Deviations of Nasal Septum.—J. W. Wood discusses this subject and describes the operation of submucous resection.

Tonsillar Calculus.—J. M. McCarthy reports the case of a man aged 30 years from whose right tonsil was removed a calculus consisting of calcium phosphate, and having a diameter of about 1 inch. The patient had experienced but little discomfort from the presence of this calculus.

The Induction of Artificial Pneumothorax in the Treatment of Pulmonary Tuberculosis.—H. Rhodes states that the indications for this treatment are: (1) Pulmonary tuberculosis limited almost, if not entirely, to one lung; (2) recurrent hemoptysis if at all severe; (3) continued fever, cough, and general increase of disease on one side, while the other lung is healing, or only slightly affected. Slight inactive disease in the fairly sound lung is not a contraindication.

Mechanical Effects of Left-Sided Pleural Effusion.—N. C. Rutherford reports a case illustrating these effects, which included displacements of the thoracic and abdominal viscera.

Creatin and Creatinin in Metabolism.—W. H. Thompson and T. A. Wallace, as the result of their experiments, are inclined to believe that creatin is probably concerned with the liberation of energy from carbohydrate material in muscle, and that creatinin is an end product of this metabolism in mammals.

Hodgkin's Disease.—Ziegler refers to the notable advances in our knowledge of malignant growths of the lymphatic system. These are anatomo-pathological in character, for we are still ignorant of the causal moments. Conditions once known as pseudoleucemia and lymphosarcoma seem to be retiring in favor of more clearly characterized affections. The great majority of conditions hitherto thus designated are now classed under granulomata of a malignant character. The author has recently published a monograph on Hodgkin's disease as thus conceived, and the present article represents a synopsis of it. This disease is a chronic infection attacking and peculiar to the lymphnodes and lymphoid organs like the spleen and thymus. It is spread essentially through the lymphatics, but terminally is capable of infecting all the tissues through the blood. It occurs at all ages, but is most common between 20 and 35 and twice as common in males after the tenth year of life. It may, therefore, bear a definite relation to man's mode of life. It occurs without predisposition and the robust are by no means exempt. It may begin in any isolated group of lymphnodes, and even in the lymphoid structure of ordinary tissues (nasopharynx, mouth, intestine, lacrymal and salivary glands); also in the spleen, thymus (as persistent thymus). As a rule the only reaction caused at first is that due to compression of neighboring structures; but in some 12 per cent. there is a distinct general reaction characterized by cutaneous and mucous irritation, as shown by itching, exanthems, cough, diarrhea, and disturbances of sight and hearing. The local lymph swellings may persist unchanged for years and even retrograde. The natural tendency, however, is to generalization. Eventually fever, anemia and cachexia supervene. A more or less characteristic blood count develops and this differentiates the affection from true lymphosarcoma, which further never causes visceral metastases.

Diet in Nephritis.—Kakowski writes largely in the interest of tomatoes as a dietetic article in the various forms of chronic nephritis. The main reliance is placed on the following foods: Milk, milk porridge, butter, black and white bread, macaroni, potatoes, oatmeal and analogous substances. The tomato is abundant, cheap, and easily preserved. It may be prepared in a great variety of dishes —may be eaten raw in substance and juice, made into sauces, soups, etc. Canned tomato soup is specially recommended. This is sometimes falsified or intentionally combined with pumpkin, pears, etc., and coloring matter added to simulate the full tomato color. The product, however, is not injurious. Tomatoes are recommended for gout as well as nephritis. The composition of the fresh article

shows that it is remarkably poor in nitrogen, and contains but a little over 6 per cent. of solid matter, over half of which is sugar. The acidity is due to citric and malic acids. Tomatoes are very poor in saline matter and this poverty in salts and nitrogen is believed to render them of value in nephritis. No definite ration is prescribed beyond the fact that the substance should be eaten three times daily in company with bread. Beside their food value they give zest to insipid foods like bread and macaroni, and are even believed to have alterative powers.

Action of H_2O_2 on Digestive Enzymes.—Walbum has recently investigated this subject, which is timely, since H_2O_2 and other superoxidized substances are sometimes prescribed inwardly. He found that weak solutions (0.08 per cent.) destroy the salivary diastase, but do not in the least interfere with the activity of pepsin or trypsin. On the other hand the rennet enzyme is completely destroyed by a certain concentration, the great sensitiveness of this and the diastase to the action of H_2O_2 standing in marked contrast with the complete immunity of the proteolytic enzymes.

Chemotherapy of Pneumococcus Infection.—Morgenroth and Levy have already published some results obtained in treating pneumococcus infection in mice with an alkaloid of the quinine series, ethylhydrocuprein. They succeeded in both preventing and arresting the infection by this means. This means nothing less than this—for the first time science has been enabled by internal exhibition to destroy bacteria in animal tissues without prejudice to the integrity of the latter. In addition to the drug in question both hydroquinine (methylhydrocuprein) and quinine itself were employed for the same purpose; but these fell far short of the first named in bactericidal quality. The power of quinine as a prophylactic in this respect is both feeble and inconstant. While ethylhydrocuprein might logically be expected to secure a much higher type of results as a prophylactic than as a curative remedy, the authors found that if exhibited at an optimum of time—about five or six hours after infection was apparent—a cure was obtained of a surely lethal disease in about 90 per cent. of all cases. This figure even exceeds the percentage of favorable results obtained in prophylaxis.

Treatment of Surgical Tuberculosis with X-rays.—Baisch, assistant to Prof. Wilms—who is well known for his advocacy of conservative measures in the treatment of surgical tuberculosis—publishes a series of successful results, chiefly in the various forms of diseased lymphnodes. The technique used was that recommended by Iselin last year and undoubtedly contributed much to the results obtained. The rays alone are often sufficient to cause the disappearance of simple enlarged nodes. In much enlarged and confluent nodes the result may consist only of a notable diminution in size, a paquet of glands being re solved into its individual members. When after prolonged radiation the nodes refuse to dwindle further, it is safe to assume that central caseation has already begun. A small incision is therefore made, pus if present is evacuated, and the caseous matter curetted; after which radiation is continued. In ulcerated and fistulous glands the rays are useful as an accessory.

Coli-Infection of the Urinary Passages.—Franke states that despite the great amount of work done in this field we are still unable to explain the pathogeny of many cases, especially in males. So-called spontaneous infection is often seen in the latter. It is known that the normal activity of the compressor urethræ safeguards the male from upward migration of urethral germs. It has also been shown abundantly that some lympathic communication may exist between the colon and the kidney and that an apparently descending type of coli-infection may complicate various intestinal diseases and disturbances. In some cases a hematogenous infection of enteric origin is probable, since coli bacilli are also found in many localities other than the urinary passages.

Cancer of the Prostate.—Posner shows by figures that cancer of the prostate is far more frequent than was formerly believed. When we bear in mind the frequency of enlarged prostate even as it comes to operative intervention and then note the incidence of cancerous enlargement of the organ—Mansell-Moulin's 25 per cent., Young's 20 per cent., etc.—we realize that the latter must be relatively frequent and that cancer of the organ is responsible for a large number of prostatectomies. Much effort has been expended of late years in regard to differiential diagnosis between hypertrophy and cancer in the early period of the enlargement. The best and in fact sole certain criterion is a trial excision through the perineum.

October 26, 1911.

Animal Tuberculosis and Human Pulmonary Consumption.—Kossel shows as a result of sputum examination that in 709 consumptives the bacilli in two—possibly in three—cases were of the bovine type alone. In a single case bovine and human bacilli were found side by side. In 705 cases the human type was alone present. These figures tend to show that Koch's view as to the pathogenicity of the bovine bacillus to man is essentially correct. His belief was that for all practical purposes man was infected from man and not from cattle. Were the latter all destroyed the incidence of human tuberculosis would not be affected.

Azöospermia and Syphilis.—Scheuer writes briefly yet monographically on this subject. The existence of a purely syphilitic azöospermia has been virtually denied, whether attributable to syphilis of the epididymis or to cachexia. A coincidence between a congenital or acquired azöospermia and a syphilitic history is of course possible. Casper and Fürbringer have each reported cases in which a gonorrheal epididymitis could not be wholly excluded. Remains of such were not palpable. The author has recently shown beyond doubt by means of Posner and Cohn's diagnostic testicular puncture that a syphilitic deposit, not palpable, could in all probability be properly held responsible for obstructive azöospermia. The puncture in question revealed the presence of healthy spermatozoa in the testicle, yet the seminal fluid contained none. There was a very emphatic history of syphilis with unusual localizations. The patient had come to consultation to learn whether his syphilis of two years' standing but apparently cured would forbid the procreation of children. After diagnosis he was placed for some months on the mixed treatment and at the expiration of the period—after some negative results—his semen was found to be normal. The hitherto positive Wassermann had become negative.

The Question of Sexual Abstinence.—Näcke expresses himself on this subject as follows: It is taken for granted that the libido and potency are normal. Under such circumstances temporary or even if not absolute abstinence in the full sense of the term is chiefly harmless. If the impulse to coitus is not excessive, and the mind well occupied, general health being good, the only drawback to permanent continence is the nocturnal pollutions. On the other hand marked sexual desire in a neuropathic will if not gratified aggravate the mental state by inducing phobias and imperative concepts. Actual psychoses, however, cannot originate thus. These neuropaths should marry. If this is impossible a compromise with venery or occasional masturbation, which will be the natural outcome, is not to be condoned by the practitioner as a generally applicable resource. Rather should all attempts be made to cure the neurasthenic state by appropriate general treatment.

Insurance Medicine.

SUGGESTIONS TO MEDICAL EXAMINERS.

BY THE INSURANCE EDITOR.

PERSONAL HISTORY.

Respiratory System.—The examiner cannot be urged too strongly to question the applicant closely and definitely in regard to any affection of the respiratory tract admitted by him, whether trivial or severe, since so large a proportion of deaths in adult life are brought about by these diseases. Probably, in this class of cases more than any other the examiner will experience difficulty at times in getting an accurate history, owing to the well-known reluctance of the average man to acknowledge or even believe that there was any suspicion of tuberculosis during some certain disturbance in his lungs or that there might be any liability to the development of this condition later on as a result of the attack in question.

Chronic or Persistent Cough, or Hoarseness.—Ascertain the date, duration, severity, and cause of each attack. Always ask specifically as to whether there was any suspicion of tuberculosis or spitting of blood. The applicant cannot be relied upon to help the examiner in this even if he is inclined to be honest, as an individual who has suffered from a pulmonary complaint often has a propensity to view his case in a too favorable light, a propensity so strong, in fact, that he may not deem it worth while to mention it to the examiner. When a cough or hoarseness lasting some length of time is acknowledged, the examiner is depended upon to question the applicant very closely, as well as to make an extra careful examination, in order to discover the cause and nature of the illness and assure himself that the disturbance was due to simple nasal catarrh, to an ordinary congestion of the fauces and pharynx with excess of mucus, to granulations in the vault of the pharynx which get dry and cause irritation, to a long uvula, or to a nervous or sympathetic influence, conditions common in America and of little consequence unless severe; or, on the other hand, as to whether the habitual cough or hoarseness was excited by some more serious involvement of the air passages. The applicant should be asked to describe the form of treatment followed at the time and also whether he resorted to a change of climate for a cure.

Spitting or Coughing of Blood.—Ascertain the exact date of each attack and the source of the hemorrhage. Every case of blood spitting should invariably be reported, no matter what the alleged source may be or how far the applicant is convinced that it was of no consequence. The examiner should remember that nearly every individual who has raised some blood is ready to explain that it came from the nose, gums, or "throat," from anywhere, in fact, but the lungs. The presumption, however, is always that the hemorrhage originated in the lungs, thereby giving the company the benefit of the doubt.

We have to admit, nevertheless, that blood may come from the lungs when there is no tuberculosis present, as a result of traumatism or some violent effort, but an hemoptysis should not be looked upon as accidental unless distinctly coincident with some injury inflicted or some violent physical exertion made at the time, and it should also be borne in mind that, even if it did occur with unusual exercise, the hemoptysis may have been caused by the breaking down of tissues weakened by disease and which would have withstood the shock if they had been in a healthy condition.

Again, there are cases in which the hemoptysis was an early symptom of tuberculosis, but the attack proved abortive and the applicant apparently recovered, the process of recovery consisting in an encapsulation of the diseased tissue, which, as is usual in such instances, contains tubercle bacilli, and the condition should, therefore, be termed one of latency rather than of recovery. The danger of autoinfection in such a patient is so great that the risk will not be insurable until many years have elapsed if at all.

If there is a history of the typical rusty sputum of pneumonia, the full details will be wanted at the home office, especially the duration of the attack and the nature of any complications, so that tuberculosis can be positively excluded.

The practice usually observed in acting on cases of blood spitting is to accept them after a period of about ten years has elapsed since the attack, provided that there was no suspicion of tuberculosis, that the applicant has not been subject to other disturbances in the respiratory tract, and that the physique and family history are satisfactory. This action is based upon the assumption that the hemorrhage was accidental or from some source outside of the lungs, and that ample time has been allowed for any tuberculosis present in the beginning to assert itself. Among the cases acted upon in this way there will possibly be an occasional one of the doubtful variety already referred to, in which the preliminary attack of tuberculosis aborted, leaving only a small scar extremely difficult or even impossible to discover in the physical examination.

Bronchitis.—Ascertain the number of attacks with the date, duration, and severity of each one, and investigate carefully as to whether there was any hemoptysis or suspicion of tuberculosis. If it is certain that the attack was due to an ordinary cold, it may be considered unimportant unless other attacks have occurred. Frequently recurring bronchitis, even if not complicated by tuberculosis, naturally impairs the expectation of life and will usually afford grounds for postponement or rejection.

Pneumonia.—Give the date, duration, and complications of each attack. It is not a good practice to accept these risks unless from six to twelve months have elapsed since the attack, and the applicant has fully regained his former weight and health and has not suffered from serious complications or other recent attacks. The length of the period of postponement will depend largely upon the season of the year. If winter is coming on it is wiser to delay the acceptance of the risk until the following spring, but if the applicant has the summer immediately before him he may be safely insured in six months after the pneumonia, everything else being favorable.

Pleurisy.—The approving officers at the home office will not be in a position to act finally on a case in which there is a history of pleurisy until the date, duration, and severity of the attack are known, what form it assumed and whether there was any suspicion of tuberculosis. It cannot be contested that the tubercular nature in a large percentage of the cases of pleural effusion and even dry pleurisy has been established, and that pleurisy may sometimes be the first expression of tuberculosis. If the exudate was purulent the problem

usually to be considered is the amount of impairment of the lung from collapse with the subsequent lowering of the vitality of the individual. The permanent damage to the lung and the consequent falling of the chest wall are apt to be more pronounced and bronchial affections are more common in after life, if the empyema occurred after the age of twenty.

The examiner should be suspicious when a history of pleurodynia or intercostal neuralgia is admitted, as in many of these cases the real disease was pleurisy, dry or with a small effusion. The writer has just had occasion to review a death claim in which it appears that the attending physician at first attributed the symptoms to intercostal neuralgia; soon, however, he changed his diagnosis to one of pleurisy and the patient died at the end of eighteen months from pulmonary tuberculosis.

Consumption.—A history of pulmonary tuberculosis will always lead to rejection even if the applicant has fully recovered.

Asthma.—Give the frequency, duration, cause, and severity of the attacks, and the date of the last attack. Also ascertain whether the spasms are growing milder and less frequent. If it occurs only during attacks of hay fever this fact should be reported, as the disorder is not seriously considered in such cases. All these data are necessary before intelligent action can be taken at the home office.

Dyspnea.—The applicant should always be asked if he has had any shortness of breath and, if so, the date and circumstances under which it took place. The causes are so numerous and well known that the enumeration of them is not necessary.

Prevalence of Circulatory Diseases.—E. W. Dwight states that the most serious problems which present themselves to-day to the medical side of life insurance companies are in connection with the subject of circulatory disease. While statistics show a great improvement in mortality as a whole, the increase in the expectation of life has taken place among the younger ages. While the proportion of individuals reaching the age of thirty has increased, the proportion of those of that age who live to be seventy has not only relatively, but also actually, diminished. Census statistics show an increased death rate from circulatory diseases with the exception of pericarditis, which belongs more properly in the infectious group, in which there has been a diminution in the death rate. Between 1904 and 1908, in the entire country, there has been an increase in deaths from circulatory diseases of 7 in 100,000 population. Statistics compiled by an insurance company with which the author is connected, which company has been in business since 1843, show that 54 per cent. of the deaths of policy-holders in that company occurred from the following five diseases: heart disease, arteriosclerosis, pulmonary tuberculosis, pneumonia, and nephritis, in the order given. There has been a progressive increase in the deaths from circulatory disease from 10 per cent. in the first decade (1844 to 1854) to 45 per cent. in the last six years (1904-1910). For the entire period from 1844 to 1910 New England leads the list of mortality from circulatory diseases. Insurance companies decline about 10 per cent. of those who apply to them, and during the year 1910 of those who were declined by the author's company one-half were declined on account of circulatory diseases. New England surpasses all other sections of the United States not only in the actual mortality from circulatory diseases, but also in the relative increase in such diseases during the past few years.—*Boston Medical and Surgical Journal*, November 2, 1911.

Injuries of the Abdomen.—Richard v. Hippel continues his consideration of this subject. He says that the stereotyped description of dullness in the right flank as due to injuries of the liver and of that in the left flank as due to injuries of the spleen is not at all applicable to all cases. The dullness due to the blood effusion may be found anywhere, according to the various positions of the body assumed after injury. Liver dullness at first is unchanged; soon after injury it may be increased because of the collection of blood near the liver, later it may diminish because of the developing meteorism or dislocation of the liver itself. With the development of peritonitis liver dullness progressively diminishes. The same signs may accompany injuries of the spleen. Fortunately, however, it is not important to decide which organ is the seat of injury and hemorrhage, for an abdominal section is indicated in any case. Surgeons, too, should not be so inclined to wait until the symptoms of shock have entirely subsided. Shock will usually disappear with the cessation of hemorrhage, and frequently this stilling of hemorrhage can only follow an operation.

Injuries of the stomach usually give signs of free air in the peritoneal cavity and a metallic percussion note or simple hyperresonance, changing in site with change in position of the patient, should be diligently sought for. Circumscribed dullness, if found, should be immediately marked out on the abdominal wall; it may be due to an exudate and the increase in size may clinch the diagnosis. Larger areas of dullness usually mean perforation of the small intestine with the infection of the peritoneal cavity by a considerable quantity of fecal material. Of course, none of these signs may be present in any given case. If, a short time after injury, the pulse is quickened, tenderness and reflex spasm of the abdominal muscles have appeared, there is spontaneous pain on deep inspiration, and the patient has become somewhat restless, injury of the intestines must be suspected, if there are no signs of extensive internal hemorrhage.

Ruptures of the urinary bladder are usually accompanied by fractures of the pelvis. Direct injury may rupture an overfilled bladder and this usually happens in drunkards. Vesical tenesmus, ineffectual or resulting only in the appearance of a few drops of blood at the meatus, is a very frequent symptom. Catheterization usually confirms the diagnosis; the difficulty is in deciding whether extraperitoneal or intraperitoneal rupture has taken place. V. Hippel closes his lengthy paper with the urgent advice to send all patients in whom an intraabdominal injury is suspected to a hospital, so that immediate operation may be performed if the suspicions are confirmed by further study of the symptoms.—*Zeitschrift für Versicherungsmedizin*, September, 1911.

The Liability of Farm Laborers to Accidents.—A systematic investigation into the causes and prevention of industrial accidents, carried on in Germany during the past twenty-five years, has revealed what would be without further explanation the rather surprising fact that agriculture suffers more from accidents than any other occupation. Of the total number of mishaps resulting in temporary disability, 45 per cent. occur in agriculture, 9 each in iron and steel trades and in building operations, and 8½ per cent. in mining. Modern methods also increase the risk of the occupation, for Canadian records show that the percentage of deaths following accident increased steadily from 11 in 1904 to 20 in 1909, while in mining there had been much fluctuation, but apparently no permanent increase. The fact is, however, that these figures are misleading, for the number of agriculturists in Germany is nine times that of men engaged in the building trades, so that actually those in the building trades suffer four times as many accidents as farmers—as would naturally be supposed.

Society Reports.

MISSISSIPPI VALLEY MEDICAL ASSOCIATION.

Thirty-Seventh Annual Meeting, Held at Nashville, Tenn., October 17, 18, and 19, 1911.

THE PRESIDENT, DR. ROBERT H. BABCOCK, CHICAGO, IN THE CHAIR.

AFTER an invocation by Rev. James I. Vance, Pastor of the First Presbyterian Church, addresses of welcome were delivered by Dr. George H. Price of Nashville on behalf of the local medical profession, and on behalf of the citizens of Nashville by Mr. W. R. Cole.

These addresses were responded to on behalf of the association by Dr. Albert E. Sterne, Indianapolis, Ind.

Pellagra; Its Epidemiology.—Dr. R. M. GRIMM of the Marine-Hospital Service stated that an investigation was made during August, 1911, in the counties of Whitley, Knox, and Bell, Kentucky. Time was spent in visiting and in studying the cases clinically; in studying the economic and sanitary conditions on which the pellagrins were living; in determining the topographical environment of the homes of the pellagrins; in making inquiries regarding the water and food supply; the relation to other cases and to heredity, and regarding any condition or circumstances which at the time seemed pertinent. The total number of cases of pellagra in the three counties, as he found it in August, 1911, and the number which he included in his official report to the Surgeon-General, was as follows: In 102 cases the diagnosis was positive. In 20 cases the diagnosis was probable, and in 18 cases of pellagra there were three deaths. The cases were diagnosed positive only when the three cardinal syndromal symptoms were present, or when there were definite histories of them. Of the 140 cases, he was able to see only 51. Of these 51 he was able to find only 16 who were then living in the homes in which they resided at the time when they noticed the first symptoms of the disease. With one exception the families of the 16 pellagrins gave a history of using surface or spring water. No observations were made in this investigation which would lead one to suspect that the disease was hereditary. So far as he was able to determine, corn products, in one form or another, had been used exclusively by all of the pellagrins. The corn meal used by the families of the miners in this region was obtained almost exclusively from the stores of the coal-mining companies. The corn meal was not of the best quality.

The Prevention and Eradication of Bubonic Plague.—Dr. W. C. RUCKER of San Francisco, Cal., said that plague was primarily a disease of rodents and secondarily and accidentally a disease of man. Man's safety from the disease lay in the exclusion of the rodent and its parasites. This was the basis of all preventive and eradicative work. If man could live in rodent-free surroundings he need have no fear of plague, because if there were no rodents, there could be no rodent parasites, and for all practical purposes the flea might be considered as the common vector of the disease from rodent to rodent and from rodent to man. The eradication of bubonic plague, therefore, meant the eradication of rodents. Dr. Rucker then discussed plague eradication and plague prevention. In the city the fight was directed against the rat and its parasites, and aimed to prevent the spread of the disease from them to man. In the country all measures followed the same general lines as in the city and were modified only to meet the existing conditions, such as the species of the rodent to be combated, the density of the population, and the different character of the buildings. The work of prevention was directed against the rodent and its parasites lest they imported and nourished the seeds of pestilence, later to distribute them to mankind. He described the various measures to be employed for the extermination of rats.

Preventive Vaccination Against Typhoid Fever.—Dr. W. S. HARPOLE of Chicago reviewed the history of typhoid vaccination, some of the results of vaccination against typhoid fever, and discussed the application of it to the practice of medicine. Recently in this country vaccination had been done in many hospitals and asylums, where nurses, patients, doctors, had been protected. Notable were the experiences of Richardson and Spooner in the Massachusetts General Hospital. They stated that from 1902 until 1906 twenty-six nurses contracted typhoid fever, and that for each case of typhoid fever treated a nurse contracted the disease. In 1909 and 1910, under vaccination, no cases of typhoid fever occurred among the nurses of the Massachusetts General Hospital. The experiences of our army and of hospitals and asylums were sufficiently convincing of the value of this vaccination. Typhoid vaccination was done by the injection of killed cultures of the typhoid bacillus. The germs were usually killed by heat. All persons who were in contact with typhoid cases, as physicians, nurses, hospital attendants, and laboratory workers, should be vaccinated. Children and young people going to the country for the summer should be protected.

The Medical Aspect of Chronic Typhoid Infection.—Dr. WILLARD J. STONE of Toledo, Ohio, stated that not only should individuals who were typhoid carriers receive appropriate vaccine treatment, but all individuals, including physicians and nurses, whose duties required the attendance and care of typhoid cases should receive immunizing treatment. By this procedure many individuals otherwise destined to become chronic carriers might secure protection which would prevent in themselves the possibility of cholecystitis or other late manifestations as well as avoid the possibility of becoming a source of danger to others. Such treatment had been found efficient and productive of little discomfort. Nurses, orderlies and physicians should be regularly immunized at intervals of two or three years, as should all others exposed to endemic or epidemic outbreaks. When typhoid bacilli had produced clinical or bacteriological evidences of cholecystitis, it was doubtful whether vaccine treatment would of itself be of avail, surgical drainage of the viscus then being indicated. On the other hand, appropriate vaccine treatment in individuals showing evidences of intestinal or urinary tract perpetuation of the bacilli, without cholecystitis during convalescence from disease or subsequently, should be given the opportunity of vaccine treatment. Not all would be cured, but the bacilli would disappear in some instances. Chronic carriers who had been treated by vaccines should be under the control of the local board of health and furnished employment, if necessary, which would not require the handling of food products.

Diseases Produced by the Colon Bacillus; Diagnosis and Treatment.—Dr. FENTON B. TURCK of Chicago said the etiology of diseases did not sufficently interest the American physicians and surgeons, hence remedial measures were directed to the treatment of symptoms, and frequently the surgeon was content with the removal of gallstones, appendices, and ulcers, etc., without sufficient interest in the causes of these complaints. Consequently many discouraging reports of the end results of many of these abdominal operations were published. In his experiments in producing peptic ulcer in dogs, by daily feeding them with large bouillon cultures of the *Bacillus coli communis*, he found that not only peptic ulcers were formed in the stomach and duodenum, but lesions in the liver, gallbladder, kidney, cecum, and other organs, while, at the same time, none of the microorganisms was found in the blood or the tissues. The colon bacilli developing in the intestines broke down and set free their endotoxins which entered the circulation and acted as a reducing agent; hence, autolysis and erosions appeared, resulting in peptic ulcer in the stomach and duodenum, and also initiating

gallbladder disease, pancreatitis, appendicitis, pyelonephritis, cystitis, and other surgical diseases which were already recognized clinically as caused chiefly by the colon bacillus. Not only surgical diseases, but many medical diseases masquerading under various names were now recognized as colon bacillus diseases. The treatment was directed to, first, the reduction of the virulency of the colon bacillus in the intestines by dietetic measures and the restoration of the functions of the stomach and intestines, especially the motor functions, and, second, to the increase of the means of defense by increasing the antibodies in the blood and tissues of the patient. Autogenous vaccines introduced subcutaneously, intravenously, by mouth, colon, or into the bladder or pelvis of the kidney as the case might require, should be employed. Modified vaccines, made by injecting the cultures into fetal pigs, incubating twenty-four hours, expressing the serum fractionally sterilized, and injected into the patient, were an active, valuable treatment in certain stubborn cases. *Bacillus coli* serum was the most active and was useful in small doses in connection with vaccines. Cases reported of ulcers of the stomach and duodenum that had had one or two previous operations were cured by these combined methods; also cases of gallbladder disease that had been operated upon without relief; others that had had appendices removed and still complained of general distress and pain in the cecal region were completely cured. Patients with ulcers that were too weak for operative procedure were cured as well as ordinary medical ulcer cases; neurasthenia, migraine, and a number of cases of epilepsy. Cases of pyelonephritis were cured by the combined direct and indirect methods, by injection subcutaneously and directly into the pelvis of the kidney through the ureteral catheter. It was over three years since this combined method of treatment was first used, and it had proven that the cures were permanent where the treatment was completely carried out.

Diagnostic Aids in Surgery of the Renal Pelvis and Ureter, with Special Reference to Pyelography.—Dr. W. F. Braasch of Rochester, Minn., spoke of the value of the radiograph and the necessity for further data to interpret correctly the *x*-ray plate. The value of shadows of abdominal viscera was not great. The data gained through the use of the cystoscope aided in interpretation. Through meatoscopy one might see evidence of stone, but secretion was often misleading. One might obtain evidence by means of the ureteral catheter. Obstruction by stone in the ureter was found in over two-thirds of the cases, and stones were passed in one-half of the cases. The stylet in the ureteral catheter when radiographed might be of value, but it might give an erroneous impression and often be insufficient. With pyelography one might be able to demonstrate changes in the outlines of the pelvis and ureter which accompanied most surgical conditions of the kidney and ureter. Hydronephrosis might be accurately determined by the pyelograph. It was particularly valuable with small distension and with marked constriction of the ureter. Inflammatory dilatation varied in extent from slight changes of pyelitis to those of pyonephrosis. By using these data one was able to identify renal shadows by inflammatory changes seen in the pelvis and ureter. Stone in the ureter was recognized by the mechanical dilatation above it. Deformity caused by tumor of the kidney might be demonstrated in about two-thirds of the cases. One should also use methods to differentiate tumors existing in other viscera. Congenital anomalies, such as duplication of pelves or ureter, horseshoe kidney, etc., could be demonstrated clinically. There was not as yet a widespread adoption of the pyelograph, largely because of a lack of technical facilities. There was never permanent injury resulting from its use. The diagnosis in urinary tract conditions should be a part of the general abdominal diagnosis.

Dr. John T. Geraghty of Baltimore said he had used this method of examination for about a year and a half, and had found it of the greatest value in a certain class of cases. It gave a most graphic and striking illustration of the stomach, dilatation of the calyx, twists of the ureter, etc. So far as the kidney and pelvis itself were concerned, he had not been able to get as much information from it as Dr. Braasch had done. With the use of the ureteral catheter, with the employment of the pyelograph to estimate the renal function, and with the chemical and microscopical characters of the urine, one could place kidney surgery on just as accurate a plane as any other branch of medicine or surgery.

Dr. Braasch, in closing, said that, with reference to the use of the pyelograph in estimating renal function, Dr. Geraghty had misunderstood him in some respects, because all realized the value of the various functional tests, particularly the phenolsulphonephthalein test, and he did not use the pyelograph as a routine measure with which to estimate the renal function.

The Diagnosis of Prostatic Obstruction.—Dr. Bransford Lewis of St. Louis outlined the conditions very briefly which gave rise to obstruction at or near the vesical neck. He had been in the habit of considering the following features as essential in the diagnosis of such conditions, not only for the analytical study of the case, but as a working basis for treatment: 1. Hypertrophy or not. 2. If so, was it causing obstruction? 3. The amount of obstruction so produced. 4. The form and nature of the condition producing the obstruction. 5. The physical and functionating condition of the allied organs, particularly the kidneys and cardiac system. All of these points should be considered and determined accurately before attempting to decide as to the treatment or operation, except for such measures as emergency treatment might call for to relieve acute retention or sepsis, etc. There were two chief modes of studying a case for arriving at a diagnosis: analysis of the history and symptomatology and the physical examination. Of the two, the physical examination was by far the more important and enlightening. There had been no more brilliant or satisfying achievements in the whole field of medicine than had been wrought by surgery of prostatic obstruction in the past decade. It had brought order out of chaos, had turned misery into comfort for the aged prostatic, and it had been a well-rounded and precise diagnosis that had been largely instrumental in attaining these results.

Cancer of the Prostate.—Dr. Robert C. Bryant of Richmond, Va., said that at present there were several tests for cancer which were being tried out and perfected in the laboratory. Some of the more significant were: 1. The hemolytic tests which were being investigated particularly by Crile. 2. The meiostagmin reaction (Ascoli) consequent upon a diminution of surface tension of solution of the serum of the patient when the extract of carcinoma was added to it. 3. The antitryptic power of the blood. 4. Colloidal nitrogen of the urine. None of these tests was final and absolute, and until they were we could never hope to be able to diagnose clinically these precancerous cases. Primary cancer of the prostate might follow one of two general types, namely, the scirrhous and the glandular. Cancer was not infrequently associated with beginning hypertrophy; it might originate in a normal and atrophic gland, or in an organ which had been the seat of a chronic prostatitis. One lobe or the entire gland might be involved. The infiltration might form foci so small as to be detected only by the microscope. Carcinoma of the prostate did not result as a degeneration of a previously benign adenomatous process. In every case of senile prostatic hypertrophy the fact of the possible existence of carcinoma must be constantly borne in mind. The prostate itself caused no symptoms in the early stages of carcinoma.

The subjective symptoms were referable to the bladder and pelvic organs; the invasion of the disease was so gradual, and the symptoms were so progressive, that there was an unconscious adjustment of the patient to the condition. The treatment was divided into preventive and curative. Medical treatment was not to be entertained. There would seem to be also but little virtue in the *x*-ray, Finsen or radium therapy. The author quoted Künmell as maintaining that bilateral castration was the operation of choice. In 22 cases of 26 operated upon the prostate was removed and the patients regained the bladder functions. The suprapubic operation was to be condemned as the prostatic urethra came away and gave an unusually good opportunity for the escape of carcinomatous juices. In the second stage of carcinoma of the prostate the operator exercised his judgment for surgical attack upon the degree and type of pathological invasion.

The Influence of Stricture of the Urethra on the Development of Hypertrophic Changes in the Prostate.—Dr. Hugh Cabot of Boston discussed the theory of the relation between stricture of the urethra and absence of hypertrophy. He spoke of the importance of the recognition of the absence of hypertrophy of the prostate in cases of stricture. He drew the following conclusions: 1. That stricture of the urethra was markedly antagonistic to the development of hypertrophy of the prostate, owing to the long-standing chronic prostatitis which it caused; that, therefore, no case of stricture of the urethra in later life, in the presence of enlargement of the prostate, might be assumed. 2. That the recognition of this fact was important in the management of retention of urine in later life, and that it had not been sufficiently understood. 3. That the management of retention of urine, due to stricture, and that due to the prostate were radically different and had a markedly different prognosis. He reported thirteen cases.

Dr. E. G. Mark of Kansas City, Mo., stated that we could still further add to the comprehensive diagnosis of hypertrophy of the prostate by means of bimanual palpation. Where there was obstruction, be it from hypertrophy or contraction at the neck of the bladder, one should get away from the idea that the residual urine was increased. In contraction of the vesical neck we were dealing with a neck below the age of those patients in whom we dealt with hypertrophies. We had a compensatory hypertrophy of the musculature of the bladder, and, therefore, a lessened residuum.

Dr. L. W. Bremerman of Chicago said it was not difficult to make a diagnosis of carcinoma of the prostate. If the pathological process had broken through the capsule, it would produce ulceration in the bladder, with hematuria and the other cardinal symptoms, and it was then too late to carry out any operative procedure which would benefit the patient. In these cases of contraction at the neck of the bladder malignancy should be suspected, and the patients should be kept for further observation.

Dr. Henry J. Scherck of St. Louis said it was important to know when to operate upon a case of hypertrophy of the prostate. He had seen a number of instances where a very large prostate which could be palpated through the rectum produced very slight symptoms of obstruction. It was not always a large prostate that caused obstructive symptoms. Not long since he unfortunately removed a man's prostate, thinking the obstruction was due to enlargement of that organ, but the obstructive symptoms did not disappear. Subsequently it was found that this man had arteriosclerosis of the spinal cord, as determined by a neurologist, which produced the bladder symptoms, and impaired the expulsive power of the bladder.

Dr. William N. Wishard of Indianapolis said that, with reference to the value of the cystoscopic findings, he could not refrain from calling attention to the fact that the cystoscope might become a clumsy instrument in the diagnosis of prostatic hypertrophy. All were confronted by the fact that the prostate changed and increased; that the urethra was usually elongated; that it also changed its angle, and in the introduction of the cystoscope, whose shaft was straight, the end of the shaft where the window of the cystoscope rested must be passed far beyond the vesical orifice and above the obstruction, or it was hard to get any view at all. If the cystoscope, with a straight shaft, was introduced into the bladder there was inevitably a considerable degree of displacement of the vesical orifice backward. The canal which, before the introduction of the instrument with a long shaft was curved, was now converted into a straight canal because of the presence of the cystoscope, and, on account of the displacement of the vesical orifice, there was produced a certain amount of bulging which was misleading. Moreover, the appearances observed through the cystoscope from time to time in some cases varied greatly.

Dr. W. F. Braasch of Rochester, Minn., called attention to the value of urethroscopic examination in the diagnosis of hypertrophy of the prostate. He was in the habit of using a flexible instrument. It was also of value in the diagnosis of carcinoma involving the prostatic urethra. Carcinoma of the prostate in the majority of cases could be diagnosed by rectal palpation.

Dr. William Britt Burns of Memphis said that Dr. Cabot had called attention to the lack of enlargement of the prostate in the presence of stricture of the urethra. This was a point that had escaped his attention, and he would like to know how that could be verified. A short time ago he had a patient with a very tight stricture of the urethra. He was not able to introduce the smallest filliform bougie. He resorted to suprapubic cystotomy, and in going through the neck of the bladder and opening the urethra in that direction he was struck with the size of the prostate and debated for a short time as to the advisability of removing the prostate, but on account of the condition of the patient he did not do so. In that case there was a large and strong annular stricture at the neck of the bladder.

Dr. John T. Geraghty of Baltimore had been interested in studying both the hypertrophied and carcinomatous prostate, and he had found on examination that carcinoma of the prostate did not arise from a degeneration of the hypertrophied tissue, but it occurred in the portion of the prostate that was left behind. The posterior commissure never underwent hypertrophy, and one would find there a plateau of tissue when cancer came, and when associated with hypertrophy he would find cancer on the posterior surface. This was a point of practical importance. When one was doing perineal prostatectomy and had to cut through a dense layer of tissue before he came to the typical hypertrophied lobules, he might be sure he was dealing with cancer because it was the only condition which would give that picture, and it would help him in making a diagnosis if he had not done so before operation.

Dr. William Billington of Birmingham, England, said, with regard to the operative treatment of hypertrophy of the prostate, that in England the suprapubic method was practised more extensively than the perineal. Very large, soft adenomatous prostates could be easily enucleated through a suprapubic incision, and the patients did well. The cases of small carcinomatous prostates, and those with contraction at the neck of the bladder, presented grave difficulties if one attempted to enucleate them by the suprapubic route. He should, on his return to England, give more serious attention to the perineal route for the removal of the enlarged prostate.

Operative Treatment of Gonorrheal Epididymitis.—Dr. Francis Hagner of Washington, D. C., said he did

not advise operation on every case of gonorrheal epididymitis, as the milder forms often recovered promptly under appropriate expectant treatment. Until operative procedures were resorted to in acute gonorrheal epididymitis very little seemed to have been known of the gross pathological appearance of this condition. In some cases on exposure of the epididymis multiple abscesses could be distinctly made out before puncture; in others abscesses could not be made out until punctures were made. Eighty per cent. of his cases had had pus present in the epididymis, varying from a few drops to one and twelve drams, and yet the textbooks on surgery stated that gonorrheal epididymitis very rarely went on to suppuration. At the line of juncture of the epididymis and testicle, an incision from six to ten centimeters long was made through the skin and parietal layer of the tunica vaginalis. After the serous membrane was opened all the fluid was evacuated and the enlarged epididymis examined through the wound. The testicle with its adnexa was delivered from the tunica vaginalis and enveloped with warm towels. The epididymis was then examined and multiple punctures made through its fibrous covering with a tenotome, especially over those portions where the enlargement and thickening were greatest. The knife was carried deep enough to penetrate the thickened fibers of the capsule, and entered the infiltrated connective tissue. When the knife was through the thickened covering of the epididymis a very marked lessening of resistance would be felt. If pus was seen to escape from any of the punctures the opening was enlarged and a small probe inserted in the direction from which the pus came; then by a backward and forward motion of the probe the opening was enlarged and the pus was allowed to escape. By this method he believed there was less danger of injuring the tubes of the epididymis than by cutting with a knife. If the probe was passed in pus would be evacuated by light massage in the region of the abscess and a fine-pointed syringe was used in washing out the cavity with a one to one-thousand bichloride of mercury solution followed by physiological salt solution. The testis was then restored to its normal position, and in every case the tunica vaginalis was thoroughly washed with a one to one-thousand bichloride of mercury solution, followed by normal salt solution. The incision of the tunica vaginalis was lightly closed with a running catgut suture, a cigarette drain of gauze was then passed through the lower angle of the incision in the tunica vaginalis down to the epididymis, the skin being brought together with a subcutaneous silver wire suture; silver foil and a sterile dressing were now applied and the parts supported by a wide T-bandage. Dr. Hagner and his assistant had operated on sixty-one cases by this method, and he stated that the more experience he had with the operation the more he felt that all severe cases should be treated by epididymotomy. The average time that his patients had been confined to bed had been about four days.

Dr. J. W. Handley of Nashville said he had had occasion several times to make incisions in the tunica vaginalis in cases of gonorrheal epididymitis, and had given his patients relief, but he had had very little experience with the operation which had been described by the essayist.

Dr. Hugh Cabot of Boston said he had operated on about thirty cases by the method described, with gratifying results. He laid stress upon the results to the gonorrheal process by drainage of the epididymis, because it had seemed clear that in a certain proportion of cases—he should say 25 per cent.—drainage of the epididymis very definitely shortened the attack.

Dr. Joseph Rilus Eastman of Indianapolis said he would like to know whether Dr. Hagner had found the colon bacillus in any of his cases of gonorrheal epididymitis. He had found colon bacilli in abscesses which ensued upon what seemed to be a gonococcal epididymitis.

Dr. Perry Bromberg of Nashville stated that shortly after Dr. Hagner described his method in the "Annals of Surgery," in 1908, he tried it on one case, and the relief afforded was so great that he had since adopted it as a routine method in teaching. He had done the operation now more than twenty-five times, and his results had been everything Dr. Hagner had claimed for the operation.

Dr. Hagner, in closing, and in replying to Dr. Eastman, stated that he had not found the colon bacillus in a single case of gonorrheal epididymitis, but he did not deny that it may have been found by others.

Calculous Anuria.—Dr. Dean Loree of Ann Arbor, Mich., read a paper on this subject in which he reported a case on which he had operated. The interesting points in it were: 1. The operation confined the anuria to the period of forty-seven hours. 2. The patient had passed through a short tolerance period and had come to operation shortly after the first symptoms of uremia had appeared. 3. The Röntgen ray plates proved of no value in the diagnosis, or in the selection of the less occluded side. 4. This was in all probability a case of bilateral calculi with simultaneous occlusion, for the following reasons: Two attempts at ureteral catheterization had resulted in failure, the catheters having been passed about the same distance each time. Another reason was that following the second nephrotomy the wound discharged freely until the passage *per urethram* of the third calculus which occluded the left ureter and subsequently the passage of the fourth calculus, which in all probability occluded the right ureter.

Relation of Renal Activity to Surgical Operation.—Dr. E. O. Smith of Cincinnati stated that the success or failure of a major operation depended largely upon the activity of the kidneys, barring faulty technique, and bad surgical judgment of the operator. The functional activity of the kidneys might be influenced by the shock incident to a major operation, by the anesthetic, by trauma to one or the other kidney, by calculi, or by urethral obstruction from any cause. There were three distinct periods of every surgical case that required special care and attention. The preoperative period, the operation, and the postoperative period. It was best to make a further study of the functional activity of the kidneys before operation. This was based upon the observations that normal kndneys removed the circulation of certain products that had been introduced within a certain time, and that marked deviations from this time represented abnormal kidneys. Numerous tests had been suggested, but only three were now looked upon as being reliable. They were phloridzin, indigo carmine, and phenolsulphonephthalein. The most reliable and valuable of the three was the phenolsulponephthalein test as developed by Rowntree and Geraghty. Operation should be done as rapidly as consistent with good work, for the longer the operation the greater the shock, and the greater the shock the greater the circulatory disturbance, in consequence of which the blood supply to the kidney was diminished, a very apparent cause of renal activity. The surgeon should not waste any time lecturing or demonstrating an operation to bystanders the same as if he had a cadaver before him. The surgeon's duty to the patient did not end with the introduction of the last suture. A great deal could be done in the next few hours to sustain the renal activity and to prevent urinary suppression. Immediately following the anesthetic the patient should be given oxygen inhalation. In old people and bad risks this should be continued for several hours. Hiccough and persistent vomiting following operations were indicative of diminished renal activity, and should be looked upon as symptoms or a note of warning rather than an independent complication calling for special treatment. If shock and the anesthetic were reduced to a minimum and proper care taken of the patient before, during, and after operation, anuria would develop only in the desperate cases. When

anuria did occur, the best treatment was fluid introduced into the veins, sweating, and morphine. He had always used saline solutions, but he believed that Fischer's solution was very much better. Alkaline solutions were far more effectual. One must not give up if the effect produced seemed transitory, but repeat it often enough to keep up the effect until the normal output had been produced and sustained.

Dr. William N. Wishard of Indianapolis said a study of the urine prior to operation, where it was found to be abnormal, was considerably influenced by the various preoperative or preparatory measures to which Dr. Smith had called attention. The specific gravity of the urine and the percentage of urea and the general condition of the urine were helpfully influenced by drainage. In a certain class of cases in his own work he drained the bladder, where it was possible, prior to operation. He inserted a drainage catheter and left it in for two or three days or longer, if necessary, and encouraged the drinking of water, and, if necessary, the use of water that was boiled. He did not always estimate the importance of shortening the period of anesthesia in its relation to renal function, as should be done. This feature was not considered as important as it really was by the average practitioner.

Dr. Hugh Cabot of Boston asked Dr. Smith whether he gave spinal anesthesia in cases where the kidney was known to be damaged, and where he was in doubt the influence of the anesthetic would subject the kidneys to a strain which was undesirable. In his practice in the last two years in operations upon the prostate he had resorted to spinal anesthesia as the anesthetic of election where the kidney function was below a fair standard, and that fair standard was a matter of personal equation, and many patients had recovered who he felt would not have recovered under general anesthesia. He had used gas and oxygen with excellent results, and in cases of damaged heart that anesthetic was to be preferred.

Dr. Charles E. Barnett of Fort Wayne, Ind., believed that we got toxemia from absorption from the colon and from distension of gas in these cases, and more attention should be paid to these things. He believed also that the genitourinary surgeon should educate the general surgeon regarding the value of preoperative treatment in operations where the kidney had been traumatized on account of disease.

Dr. Smith, in closing, said, in regard to spinal anesthesia, he had had very little experience with it. Nitrous oxide and oxygen had been so satisfactory in the desperate cases that he had not found it necessary to resort to spinal anesthesia.

Pathology and Complications of Cholecystitis.—Dr. H. M. Richter of Chicago said that the terms cholecystitis and gallstones were not to be used interchangeably; that stone formation followed infection as an end result. When found in what was supposed to be a first attack of gallbladder disease they meant an overlooked earlier infection. There was either an ascending infection from the intestine by way of the common and cystic ducts, or a descending infection from the vascular system by way of the liver. Infection reaching the bile was enabled to exert its pathogenic action on the gallbladder wall by being kept in contact with it for a prolonged period of time. The normal reservoir-like action of the gallbladder was a sufficient factor, and it was not necessary to presuppose a pathological degree of stasis. The constant flow of bile in the ducts accounted for marked infrequency of early infection of the latter. Acute inflammation of the gall-bladder might be mild, with but slight involvement of the bladder wall, mainly the mucosa, causing the pouring out of an excess of mucus, and an excessive desquamation of its epithelium. These were the important factors in cholesterin formation and deposits, and hence the primary factor in gallstone formation. The more severe grades of inflammation were analogous to those found elsewhere, but the suppurative type was most common. Gangrene might result from severe infection or from overdistention from blocking of the cystic duct. Local traumatism by the stone with infection was the cause of ulcer formation. The extension of the stone and false diverticulum was rare. Papillary epithelial outgrowths and malignant epithelial changes occurred with sufficient frequency to be properly regarded as caused by the precedent pathological condition. Gall-tract infection, especially with stones, bore a direct causal relation to pancreatitis. Local peritonitis was the cause of adhesions involving the neighboring structures, stomach, duodenum, and colon. There was a reciprocal relation between gallbladder and appendix infections. A stone large enough to cause intestinal obstruction might pass through the gallbladder and intestinal walls by a process of ulceration and extrusion. Large stones could, however, pass by way of the greatly dilated cystic and common ducts. This true mechanical obstruction must not be confounded with the ileus of acute cholecystitis.

(To be continued.)

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, Held October 23, 1911.

The President, Dr. F. McKernon, in the Chair.

West Side Hospitals.—Dr. John A. Wyeth said that three years ago Roosevelt Hospital had discontinued its ambulance service and the New York Polyclinic Hospital, looking for a new location, decided to move to the West Side and to cover this district. They had purchased property on West Fiftieth and Fifty-first streets and had built a hospital at a cost of $700,000, intending to take up an ambulance service which should cover the district from Forty-second to Ninety-second streets. The Board of Managers of the New York Hospital has since purchased property with the intention of building at Fifty-second street and Eleventh avenue. It seemed to Dr. Wyeth that it would not be for the best interests of the people to have three hospitals so near together and he thought that the Board of Managers of the New York Hospital should be asked to reconsider their decision.

Dr. J. Riddle Goffe offered a resolution embodying Dr. Wyeth's suggestions, which was seconded.

Dr. E. Eliot Harris, Chairman of the Committee of Legislation, moved that the matter be referred to the Committee on Hospitals and Budget of the City of New York. This motion was seconded and carried.

Revision of the Constitution and By-Laws.—Dr. Charles H. Richardson presented the report of the Committee on the Revision of the Constitution and By-Laws. This report was not read as it was soon to be published and a copy sent to each member of the Society.

Nominations.—Nominations were made of Officers, Censors, and Delegates to be elected at the One Hundred and Sixth Annual Meeting to be held November 27, 1911.

X-Ray Examination in the Diagnosis of Gastric Diseases.—Dr. L. Kast read this paper. He said that, while the *x*-ray did not enable them to see the stomach itself, the contents gave an image of the outline and the changes during peristalsis and served to indicate a number of facts which might be called röntgenological symptoms. Like all other symptoms they must be based on comparison with the normal conditions of the organ. The technique consisted of giving the patient bismuth, preferably the subcarbonate, in water, or as a paste, or in a capsule, or mixed with some food like rice or apple sauce. Each of these methods should be used according to the particular diagnostic problem. The best method of examination at present was to examine with the fluoroscope

and at the same time to take pictures. If they examined the stomach of a normal person while taking a bismuth meal, they noticed that the food entered gradually, met with apparently some resistance, glided down the upper curvature, and finally rested on the lower curvature at about the level of the umbilicus. Upon becoming sufficiently filled the shape of the stomach became visible and was either hookshaped or bullhorn, both of these being physiological varieties. The shape of the stomach depended upon the height of its contents, the support given through the abdominal walls, and the tonus of the gastric musculature. There were different degrees of tonicity that occurred in individuals without digestive disturbances. These degrees were designated as hypertonic, orthotonic, hypotonic, and atonic.

There was no standard time for the evacuation of a given amount of food. Different types required normally different lengths of time for complete evacuation. Probably many cases of beginning pyloric stenosis remained unrecognized because they had only one standard for all kinds of stomachs. A dislocation of the stomach to the right or left was a röntgenological symptom indicating some pushing or pulling force and might be meteorism, ascites, tumors, or shrinking adhesions. Distortion of the pyloric portion to the right indicated adhesions as they occurred after ulcers of the pylorus or duodenum, pericholecystitis, or malignant adherent tumors in that region. A rolling up of the stomach on its shortened upper curvature was a symptom in favor of an ulcer on that part of the stomach. Another röntgenological symptom was the relation of the stomach to points painful on pressure. The differential diagnosis of abdominal tumors received valuable assistance from the following röntgenological symptoms: 1. If the tumor was outside the gastric shadow, and could be displaced without effect on the position of the gastric shadow, the tumor was extragastric. 2. If the tumor was partially or entirely within the gastric shadow and they could be separated from each other, the tumor was an extragastric one. 3. If the tumor was partially or entirely outside of the gastric shadow, but remained in spite of change of position, and was constant in relation to the stomach, the tumor might be either gastric or extragastric and adherent to the stomach. 4. If the tumor was the cause of an incomplete filling of the stomach, the borderline would help in determining the character of the tumor. An irregular indentated border signified a nodular tumor within the stomach; a smooth borderline evenly curved toward the stomach convexity signified an impression of a tumor on the gastric wall. Radiological symptoms regarding the filling of the stomach with bismuth were: (1) The constant so-called hourglass constriction which might be the effect of an old ulcer, or of a carcinoma, or of both. The ulcer usually caused a constriction with the center of the traction at the small curvature while the carcinoma more often showed the center of traction between the two curvatures. (2) An indentation of the larger curvature which was of transitory character occurred so frequently with ulcer of the small curvature that it was considered by some radiologists as pathognomonic of gastric ulcer. This transitory contraction had at times led to the diagnosis of hour-glass contraction which the surgeon could not find. (3) The significance of incomplete filling of the stomach had been considered in connection with palpable tumor. At times the tumor could not be palpated except under the guidance of the fluoroscope. Again the incomplete filling might be due to gastric or perigastric infiltration. The niche symptom of Handek, which was of recent date, was one of the most valuable symptoms and was pathognomonic of penetrating ulcers. It was characterized by a bismuth spot outside of the borders of the stomach usually near the small curvature, but in direct communication with it. It was a defect in the substance of the liver or pancreas and moved freely with the stomach but less freely than under normal conditions. As a rule it corresponded to a sensitive point. In some instances the niche symptom did not appear after the bismuth meal but became evident after the stomach was empty; the patient rested for a few minutes on his left side and then took bismuth water while lying on his right side. The following röntgenological symptoms regarding motility were useful: (1) Antiperistalsis was a reliable sign of an organic affection at the pylorus. (2) The flattening or the stoppage of the wave at a certain point was a sign of an organic lesion. (3) Increased tonus, increased force, and increased frequency of the waves were a possible sign of pyloric stenosis. The röntgen examination also enabled them to test the motor power of the stomach. The test for the evacuating power of the stomach with *x*-rays was finer and of higher value than the test with the tube excepting microscopical retention. In the opinion of the writer the niche symptom was the only one which was pathognomonic, all others must be taken in connection with collateral signs of disturbed health. It was possible to group the röntgenological symptoms in such a way as to gain valuable röntgenological symptom-complexes. By some such complexes it was possible at times to make a diagnosis purely on *x*-ray examination. This method of examination was not yet thoroughly worked out but it appeared reasonable that it should take its place among other diagnostic methods. It was well enough established to reduce the number of unnecessary explorations and to increase the number of necessary operations at an early stage of the disease.

Dr. G. E. Pfahler of Philadelphia said, in opening the discussion, that Dr. Kast had so thoroughly covered the ground that there was little left for discussion. From a fairly large experience in this line of work he could truthfully say that the more he did the more enthusiastic he became and the more confidence he gained in his findings. He also observed more possibilities of error and if these errors could be eliminated he felt sure that they could place the diagnosis of gastric disorders on a definite basis. While he believed that they could obtain more information in regard to gastric disorders by means of the röntgen examination, this did not mean that they should neglect other evidences of disease of the stomach. They should combine this method with others in order to arrive at a correct diagnosis. Dr. Kast had referred to the work of Clairmont, who had made a careful study of one hundred cases and in not one of them was a single error found at operation. In his own experience Dr. Pfahler had made the diagnosis of carcinoma of the stomach in seventy-five cases and in only one was his diagnosis not confirmed at operation. In this instance he had made a diagnosis of gastric carcinoma and at operation an ulcer of the stomach with spasmodic contraction was found. At that time, four years ago, they did not recognize the appearances of spasm of the stomach with the contraction; this closely simulated the hour-glass contraction which was due to gastric carcinoma. Dr. Pfahler closed his discussion with a lantern slide demonstration.

Dr. Eugene Caldwell said that only röntgenologists realized how frequently plates were misinterpreted; very accurate judgment was necessary to get much from the *x*-ray in stomach examinations. It was absurd for one with a limited experience to attempt to draw fine conclusions. The Germans had done much more than they had in this field of work. The fault lay with clinicians and also with medical journals which frequently did not make a careful selection of articles on this subject. They seldom published articles which were the result of laboratory work on hundreds and hundreds of these examinations. Dr. Caldwell presented a number of lantern slides.

Dr. Samuel Lloyd said that the fluoroscopic examination of the stomach with the bismuth contents and the

study of the peristaltic waves were very interesting. Whenever it was possible he took the opportunity of looking at a stomach that was coming to operation and it was surprising how much one could learn regarding the position of the stomach and the suggestions that could be obtained for operative treatment. If they were going to do a gastroenterostomy, to unite the jejunum to the stomach beyond a certain point, they were going to drain that stomach too early and would not get complete emptying of the stomach. He had been led to the conclusion that when the stomach was not occupying the position that it should occupy, but was in a more perpendicular position, the place for doing a gastroenterostomy was at the junction of the middle and pyloric third. If this operation was possible they would not get the pain and the unpleasant experiences met with after the operation formerly used.

Dr. John F. Erdmann said that one year ago he reported several cases of cancer of the stomach and he made the statement then that the *x*-ray was of little value except to inform one that the bismuth paste passed through or did not pass through the pylorus. When it did not pass through it meant that there was an obstruction which might be either from a malignant growth or from a stenosis. When the bismuth paste passed through the pylorus into the duodenum it merely indicated that the pylorus was not sufficiently stenosed to cause a complete obstruction, and it did not show whether or not a malignant growth was present. To-day, however, he was heartily in accord with Dr. Kast's statements and those demonstrations proved to him that Dr. Kast was on the right track and that one without question obtained much aid by the *x*-ray.

Dr. Max Einhorn spoke of the marvelous way in which röntgenology had progressed. He believed that whatever was not accomplished by it now would be later on. Twenty-three years ago he had attempted to transilluminate the stomach and later he had succeeded in mapping out tumors which interfered with the stomach's function. At that time he could do this only when the tumors occupied but a part of the stomach. Now tumors could be diagnosed even if they could not be palpated. In previous work the introduction of a tube into the stomach was necessary but the *x*-ray had obviated the necessity for this procedure. Dr. Einhorn said that he had examined many patients by this method during the past few years and he could corroborate all that the gentlemen who had preceded him had said. With the assistance of Dr. Cole he had taken pictures of stomachs that were filled with air and by this means they had been able to diagnose tumors that were so small as to be obscured by the bismuth.

Dr. Willy Meyer said that he considered the *x*-ray a great aid in defining and refining the clinical diagnosis of diseases of the stomach. It was important, however, to approach a case as if they were not in possession of the *x*-rays, viz., to make a diagnosis with the help of the many other methods at their disposal. Then the subsequent radiographic diagnosis should be compared with the previous findings. So far as the cardia was concerned they had to deal with strictures only, either malignant or benign, the latter due to cardiospasm or organic disease. Here by means of the sound and esophagoscope, together with the removal of a piece of the growth for microscopical examination, they could clear up a case. In malignant cases the *x*-ray could merely corroborate the presence of the stricture. The shadow would show the esophagus either partially or totally filled up according to the quantity of bismuth swallowed. Thus far the *x*-rays had not enabled them to tell what kind of a stricture they had to deal with. Probably they would yet learn to read this, for the *x*-ray was a very recent addition to their diagnostic means in these cases. The *x*-rays were of greater value in diseases of the esophagus above the cardia; there they showed a great deal of detail. Personally he would not do without them in such cases and he considered a stereoscopic view of particular value. Dr. Meyer related the history of a case on which he had operated for benign cardiac stenosis by means of thoracotomy, stripping both pneumogastric nerves off the lower end of the esophagus for several inches and infolding the walls by a single row of sutures. The case illustrated the difficulties of rendering exact diagnosis with reference to the nature of the stricture, even with the help of operative procedure, for although the sound had passed the cardia when it was clearly under the eyes of the operator and under his fingers for manipulation, the functional results were not perfect; the patients still had difficulty in swallowing and evidently did not suffer from cardiospasm, as diagnosed, but from organic stricture, due to ulceration at or near the cardia. He now expected to do an intrathoracic cardioplasty according to the method of Heineke-Miculicz, the method in use for benign stricture of the pylorus, which was a feasible procedure on account of the mobility of the cardia.

Dr. Henry H. M. Lyle made a plea for intelligent cooperation between laboratory workers, internists, röntgenologists, and surgeons, as this was essential to success and would lead to practical results.

Dr. Anthony Bassler said that Dr. Kast had shown four types of stomachs taken from *x*-ray observations made in the upright position showing the bismuth suspension in the lower region of the organ with a straight line to its upper level and a clear space beginning with a straight line below to represent the empty stomach capacity above it. According to the fluoroscopic observations of a number of stomachs this straight line of demarcation was only uncommonly seen, for the suspension splashed up or was worked around by the stomach motility toward the fundus so that this line was seldom produced as sharply as in the plates shown. Great care must be exercised in making diagnoses of extragastric tumors pressing upon the outer part of the stomach when the indentation was uniform and round. In practically all of his plates in which this was seen it was due to gases that had risen from the descending colon and collected in the splenic flexure pressing upon a low stomach. All over the country Dr. Bassler had seen these moving pictures and also foreign-made plates of the stomach motility, and he was not convinced that they represented the normal stomach and not a hypermotility. He felt sure these pictures were very much exaggerated. He advanced this opinion only after the examination of several hundred normal persons. The *x*-ray examination of gastrointestinal conditions was today the most valuable means they had, but there was the danger of mistake in that certain conditions that one would suppose must be seen were not seen, and that certain findings that looked like serious conditions were not present in the patient. With good technique the danger of these mistakes was minimized, but it was always present. The trouble was that there was a tendency with certain men to read too much into the plates in the way of imagination. They must remember that the rays traveled in straight lines, and that the anatomy must be changed in definite ways and a set of conditions must be found always present in a series of observations if they were to be of value in clinical work.

Pathological Society of Philadelphia.

At a stated meeting held October 26, Dr. Alfred Gordon exhibited a specimen of "Tumor of the Brain." The patient was a man, 28 years old, who presented symptoms of cerebellar tumor, headache, vomiting, vertigo, deflection to one side in walking, impaired vision and double choked disk. Autopsy disclosed a tumor in the left temporal lobe appar-

ently involving also the island of Reil and the third frontal convolution, although there had been no speech-defect. Drs. J. Earle Ash and Frederick C. Potter demonstrated a specimen of "Cerebellar Tumor Associated with Hypernephroma of the Kidney." The patient was a man, 32 years old, who suffered from headache, impaired vision, double choked disk and an inability to maintain himself in the erect posture. In addition to a tumor of one kidney exhibiting histologic characters of hypernephroma, a growth was found in one lobe of the cerebellum with structural characters of a glio-sarcoma. Dr. Frank A. Craig reported "A Case of Carcinoma of the Breast with Extensive Lung-involvement," and he demonstrated the specimen. The patient was a woman admitted to the Phipps Institute for Tuberculosis, with a history of carcinoma of one breast removed five years previously. She complained of cough, with watery expectoration, loss of flesh and irregular elevation of temperature, and varying dullness of one side of the chest. A diagnosis of secondary carcinoma of the lung and pleura was made, and this was confirmed at autopsy, the lung and pleura being involved in extensive and widespread new growth. Dr. Jay F. Schamberg gave a "Demonstration of the *Spirochæta pallida* by the Burri Method." A slide was prepared from the throat of a young man in a school in an interior town, a small amount of secretion being mixed with distilled water and then a solution of India ink being added, and the preparation dried. The spirochetes showed beautifully as delicate white, tortuous structures on a black background. From having been present in large numbers at the primary examination, the spirochetes greatly diminished within twenty-four hours of the intravenous injection of arsenobenzol. Also, the pain previously present largely subsided within ten minutes of the injection.

Dr. George W. Outerbridge exhibited "A Cystic Appendix Occurring in Conjunction with a Large Ovarian Cyst." The patient presented characteristic symptoms of ovarian cyst, and on operation this formation was found adherent to an enlarged and cystic vermiform appendix. The question arose whether the two processes were independent or in any way related, as both showed similarity in histologic structure. Dr. Thomas W. Hunter demonstrated sections from an enlarged lymphatic gland removed from the left supraclavicular region, the carcinomatous nature of which permitted a diagnosis of carcinoma of the stomach to be made. A mass was palpable in the left hypochondrum. Free hydrochloric acid was absent from the gastric secretion, but lactic acid was not present, nor were Oppler-Boas bacilli.

Drs. Paul A. Lewis and I. Kaufman presented a communication entitled "An Attempt to Influence the Bacterial Flora of the Intestinal Tract Specifically." The work was undertaken with a view of solving certain problems in anaphylaxis and of determining whether carriers of pathogenic bacteria are subjects of a chronic mild infection or the bacteria persist in some other relation. The bacillus pyocynaeus was employed in the experiments, but the results yielded were entirely of a negative character.

Dr. J. Earle Ash presented a communication entitled "Wassermann and Allied Reactions in the Blood and Spinal Fluid of the Insane." In a considerable number of cases of paresis, cerbrospinal syphilis, tabes, and other forms of nervous and mental diseases, with and without history of syphilitic infection, the reaction of the blood to the Wassermann test and of the cerebrospinal serum to the Wassermann test and to the Noguchi modification, and the cellular content of the serum was studied. While the results obtained from examination of the blood-serum alone were more uniformly positive than those from examination of the cerebro-spinal fluid, the most satisfactory results were secured from a combination of the several modes of examination.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

Board of Medical Examiners of the State of Oregon.

July, 1911.

ANATOMY.

1. Name and give the nerve supply of each of the muscles that move the eye.
2. Name the foramina found in the base of the skull. State the bone or bones in which each is found.
3. Describe the occipital bone.
4. Describe the formation and give the branches of distribution of the brachial plexus of nerves.
5. Through what vessels and openings would a blood corpuscle pass in going from the vermiform appendix to the lower horn of the right lateral lobe of the thyroid gland.
6. Name the structures that would be severed in an amputation of the thigh at the apex of Scarpa's triangle.
7. Give the course and distribution of the branches of the celiac axis.
8. Give the structure of the urinary bladder, and give the vessels from which it receives its blood supply.

PHYSIOLOGY.

1. Describe the different forms of muscles in the human body and where each form is found.
2. Describe the act of respiration.
3. Give the functions of the liver.
4. Describe the process of digestion.
5. Give the functions of the blood.
6. Name the most important ductless glands in the body.
7. Give normal quantity of urine passed in twenty-four hours; (*a*) give composition of normal urine; (*b*) when carbontes occur in urine is it alkaline or acid?
8. Describe osmosis, endosmosis, and exosmosis.

HISTOLOGY.

1. Give the histological structure of a long bone as seen in a cross section.
2. Name in order the histological structures concerned in the process of the formation of urine from the blood and its delivery to the pelvis of the kidney.
3. Name the corpuscular elements found in normal human blood, and give the relative number of each variety of corpuscles.
4. Give the microscopic structure of a lobule of the liver.

PATHOLOGY.

1. How would you differentiate chlorosis and pernicious anemia?
2. Give pathology of acute lobar pneumonia.
3. Describe the changes taking place in chronic interstitial hepatitis (cirrhosis of the liver).
4. Give pathology of acute infectious osteomyelitis

CHEMISTRY.

1. How would you detect the positive pole in a galvanic battery, and how would you know the negative pole in a faradic battery?
2. What is meant by the equivalence of an atom?
3. What is chlorine? What is its symbol? What is its atomic weight? What is its molecular weight? What is its specific gravity?
4. What are the antidotes for poisoning with the alkaline caustics?
5. For what is Trommer's test used, and how is it used?
6. For what is the Petenkofer test used, and how is it used?
7. What is the ultimate origin of urea in the human body, and how much is the normal daily excretion?
8. What is an alkaloid, and what is a general chemical antidote for poisoning with alkaloids?
9. What are ptomaines? Name three ptomaines? Are all ptomaines poisonous?

DIAGNOSIS.

1. Give the differential diagnosis between acute miliary tuberculosis and typhoid fever, without the Widal test. (*b*) What are the symptoms of intestinal perforation in typhoid?
2. How would you distinguish acute poliomyelitis anterior, in which the lesion involves the face and hand centers, from tubercular meningitis?
3. Give a complete picture of acute gastric ulcer.
4. What symptoms would lead you to suspect chronic interstitial nephritis without examining the urine?

5. Give symptoms of diabetes mellitus without urinary findings.
6. What symptoms would lead you to suspect abscess of the liver?
7. Give the symptoms of hyperhydrochlorydria.
8. Give physical signs of fibroid phthisis.

MATERIA MEDICA AND THERAPEUTICS.

1. Give antidotes for the following poisons: (*a*) Oxalic acid. (*b*) Corrosive sublimate. (*c*) Arsenic. (*d*) Gelsemium. (*e*) Copper sulphate. (*f*) Iodine.
2. What are the physiological effects of ether inhalations?
3. Name the incompatibles of silver.
4. Name two drugs classed under the following: (*a*) Vesicants. (*b*) Irritants. (*c*) Escharotics. (*d*) Rubefacients. (*e*) Diaphoretics. (*f*) Diuretics. (*g*) Anthelmintics. (*h*) Cardiac depressants.
5. What are the physiological effects of digitalis?
6. Give the therapeutic uses of aconite.
7. How do drugs classed as emmenagogues differ from ecbolics?
8. How much cocaine would you use for a 3 per cent. solution in a two-ounce mixture?

PRACTICE OF MEDICINE.

1. Describe the rash and give the morbid anatomy of scarlatina.
2. Give the etiology and pathological nature of acute endocarditis. If the patient recovers, what permanent pathological condition results?
3. Give the morbid anatomy of acute lobar pneumonia.
4. Differentiate neuritis from neuralgia.
5. Differentiate diphtheria from follicular tonsillitis.
6. Give the period of incubation and of eruption of the exanthemata.
7. On what symptoms would you base a diagnosis of typhoid fever?
8. Differentiate embolism and thrombosis.

DISEASES OF CHILDREN.

1. Give etiology, symptoms, prognosis, and treatment of retropharyngeal abscess.
2. Define tetanus; give causes, symptoms, and prognosis.
3. Define pericarditis, myocarditis and endocarditis. (*a*) Give causes of each. (*b*) Give diagnostic points of each.
4. How would you differentiate between pleurisy, lobar pneumonia, and empyema?
5. State the capacity of stomach in infant one day old.
6. Give etiology, pathology, symptoms, and treatment of acute gastroenteritis.
7. Having made diagnosis of a case of diphtheria, what instructions would you give to prevent spread of disease and give treatment of case.
8. Give etiology, symptoms, and treatment of membranous croup.

NERVOUS DISEASES.

1. Define thrombosis, an embolus, a cerebral hemorrhage.
2. Name a disease having its morbid lesion in (*a*) the anterior columns of the cord, (*b*) the lateral columns, (*c*) the posterior columns.
3. Give symptoms of labioglossopharyngeal (bulbar) paralysis when fully developed.
4. How would you diagnose a case of epidemic cerebrospinal meningitis?

SURGERY.

1. Bound Scarpa's triangle; mention the vessels and nerves in it, and tell how you would ligate the superficial femoral artery.
2. In an amputation of the forearm three inches above the wrist, what arteries will it be necessary to tie, and of what are they barnches?
3. What surgical landmarks of the elbow-joint would aid you by their position in diagnosing between a fracture of the upper end of the radius and a posterior dislocation of the ulna?
4. What is genu valgum? State how it should be treated.
5. What structures are divided in the operation for strangulated femoral hernia?
6. What symptoms follow division of the radial nerve?
7. Give the differential diagnosis of pelvic peritonitis and impaction of feces.
8. What are the chief surgical diseases of the groin?

OBSTETRICS.

1. Describe the development of the chorion.
2. What is the connection or relation between ovulation and menstruation?
3. Give differential diagnosis between pregnancy and ascites.
4. What is the characteristic symptom of placenta prævia? What is the proper management of the case?
5. What is meant by the term Crede's method?
6. What is the proper method of procedure, in a case of arrested labor, when the arrest is caused by interlocked twins?
7. What procedure would you follow in a case of asphyxia neonatorum?
8. What is meant by the term, and what are the causes of icterus neonatorum?
9. What are the indications that would induce you to perform podalic version, and how would you perform the operation?

GYNECOLOGY.

1. Describe in full the operation for abdominal hysterectomy.
2. Give the causes and treatment of non-specific vaginitis.
3. Symptoms and treatment of cystocele.
4. Describe operation for rectocele.
5. What benefit is derived from intrauterine applications? (*b*) What harm may follow the above treatment?
6. What are the physical signs and treatment for a prolapsed ovary?
7. What is meant by the following terms: menorrhagia, metrorrhagia, metrorrhea, amenorrhea?
8. Give treatment for menorrhagia; for amenorrhea.

EYE AND EAR.

1. Acute otitis media; give cause, symptoms, complications, and treatment; indications for opening the ear drum, give landmarks of ear drum, point of selection in paracentesis, and dangers attending the same.
2. Cause, diagnosis, complications, and treatment of acute mastoid abscess.
3. Give the symptoms, prognosis, and treatment of acute glaucoma, differentiate between acute glaucoma and iritis.
4. Give cause, symptoms, complications, and treatment of ophthalmia neonatorum.

LEGAL MEDICINE.

1. Under what circumstances may a physician be justified in producing an abortion, and how is the operation performed.
2. Give the symptoms of arsenical poisoning? How would you demonstrate that arsenical poisoning had been the cause of death in a given corpse?
3. A corpse is presented, death being caused by hypodermic injection of morphine. Tell how you would demonstrate the fact before a court?
4. A person having died from an over dose of strychnine, tell the various steps and methods you would employ to enable you to testify intelligently to the facts before a court.

ANSWER TO STATE BOARD EXAMINATION QUESTIONS.

BOARD OF MEDICAL EXAMINERS OF THE STATE OF OREGON.

July, 1911.

ANATOMY.

1. *Muscles that move the eye:* Rectus superior, rectus inferior, rectus internus, rectus externus, obliquus superior, and obliquus inferior. Of these the external rectus is supplied by the abducens, the superior oblique by the trochlear, and the others by the motor oculi.
2. See Cunningham's "Anatomy" (1909), page 166; or Gray's "Anatomy" (1910), page 123.
3. See Cunningham's "Anatomy" (1909), page 108; or Gray's "Anatomy" (1910), page 70.
4. The *brachial plexus* is formed by the union and subsequent division of the anterior divisions of the fifth, sixth, seventh, and eighth cervical and the first dorsal nerves. The union of the fifth and sixth makes the upper trunk; the seventh forms the middle trunk, and the eighth cervical and first dorsal make the lower trunk. Each of these trunks is divided into an anterior and a posterior branch. The anterior branches, from the upper and middle trunks, make the upper or outer cord of the plexus; the anterior branch of the lower trunk becomes the lower or inner cord; the three posterior branches unite to form the

posterior or middle cord. The plexus lies between the Scalenus anticus and medius.

And see Cunningham's "Anatomy" (1909), page 624; or Gray's "Anatomy" (1910), page 1031.

5. The blood corpuscles would pass from the appendix through the appendicular vein, superior mesenteric vein, portal vein, hepatic vein, inferior vena cava, right auricle of heart, through the right auriculo-ventricular opening and the tricuspid valve into the right ventricle, through the pulmonary opening and pulmonary semilunar valve into the pulmonary artery, then through pulmonary capillaries, pulmonary vein, into left auricle of the heart, through the left auriculo-ventricular opening and mitral valve into the left ventricle, through the aortic opening and aortic semilunar valve into the aorta, then into innominate artery, right subclavian artery, thyroid axis, and inferior thyroid artery.

6. Skin; fascia; muscles: Sartorius, rectus femoris, tensor vaginæ femoris, vastus externus, vastus internus, crureus, adductor magnus, adductor longus, adductor brevis, pectineus, iliacus, gracilis, biceps, semi-membranosus, semi-tendinosus, gluteus maximus. Arteries: Profunda femoris, femoral. Veins: Femoral and saphenous. Nerves: Anterior crural, obturator, sciatic, external cutaneous.

7. See Cunningham's "Anatomy" (1909), page 843; or Gray's "Anatomy" (1910), page 660,

8. See Cunningham's "Anatomy" (1909), page 1156; or Gray's "Anatomy" (1910), pages 1365 and 1367.

PHYSIOLOGY.

1. Muscles are divided into two great classes: Voluntary and involuntary. *Voluntary* muscle is striated, has long narrow fibers with cross striations and many nuclei beneath the sarcolemma. *Involuntary* muscle is non-striated, has spindle-shaped fibers, one nucleus centrally located, and no sarcolemma. The great exception is cardiac muscle, which is involuntary and also striated. *Voluntary muscle* is found in all the skeletal muscles, pharynx, diaphragm, larynx, external ear, and eye. *Involuntary muscle* is found in the alimentary tract from the middle third of the esophagus to the anus, in the ducts of glands, in the trachea and bronchial tubes, within the eyeball, the internal urinary and genital systems, circulatory (except the heart) and lymphatic systems, and the capsules of some organs.

2. *Respiration* is the process by which an interchange of gases takes place in the lungs; so that oxygen is introduced and carried to the tissues, and carbon dioxide is expelled. See Gray's "Anatomy" (1910), page 423.

The changes produced in the *air* by respiration are:

	INSPIRED AIR.	EXPIRED AIR.
Oxygen	21 per cent.	16.6 per cent.
Nitrogen	79 per cent.	79 per cent.
Carbon dioxide	0.04 per cent.	4.4 per cent.
Other gases	Rare.	Often present.
Watery vapor	Variable.	Saturated.
Temperature	Variable.	That of the body.
Volume	Varies.	Diminished.
Bacteria	Always present.	None.
Dust	Always present.	None.

3. The *functions of the liver* are: (1) The secretion of bile, (2) the formation of glycogen, (3) the formation of urea and uric acid, (4) the manufacture of heat, and (5) the conversion of poisonous and harmful into inert material.

4. *Digestion* is the process by which food is converted into material suitable for absorption and assimilation.

The different stages of digestion are: (1) *In the mouth*, where the food is crushed, mixed with saliva, and reduced to a pulp; a certain amount of starch converted into maltose and rendered slightly alkaline. Fats and proteids are unaltered. (2) *In the stomach*, where the contents are rendered acid, conversion of starch into sugar ceases, connective tissue of fats is dissolved, and fats are set free. Proteids are dissolved and peptones formed. The albuminous foods are dissolved for the most part, and a grumous mixture of peptones, liquid fats, and starches is formed, which is termed chyme, and is gradually passed through the pylorus into the intestine. (3) *In the intestine*, where the chyme mixes with the bile, pancreatic and intestinal juices, becomes alkaline, conversion of starch into sugar recommences, emulsifying of fat begins, and the undissolved proteids are converted into peptones. The diffusible peptones and salts enter the portal vein, the fat in a fine state of division entering the lacteals. In the large intestine the liquid chyme becomes more and more solid, is rendered acid by fermentative changes, and acquires the odor of feces. (From Ashby's *Notes on Physiology.*)

5. FUNCTIONS OF THE BLOOD: The *red blood cells* carry oxygen from the lungs to the tissues. The *white blood cells:* (1) Serve as a protection to the body from the incursions of pathogenic microorganisms; (2) take some part in the process of the coagulation of the blood; (3) aid in the absorption of fats and peptones from the intestine, and (4) help to maintain the proper proteid content of the blood plasma. The function of the *platelets* is not determined; it is possible that they take some part in the coagulation of the blood. The *plasma* conveys nutriment to the tissues; it holds in solution the carbon dioxide and water which it receives from the tissues, and takes them to be eliminated by the lungs, kidneys, and skin; it also holds in solution urea and other nitrogenous substances that are taken to and excreted by the liver or kidneys.

6. *The ductless glands are:* The spleen, thyroid, thymus, parathyroids, suprarenals, carotid, coccygeal, pituitary, and pineal glands.

7. The normal amount of urine passed in twenty-four hours is about 45 to 50 ounces.

The following table (from Dunglison's "Medical Dictionary") gives the average composition of normal urine:

	(PARTS IN 1000.)	
Water	950.00	
Urea	28.00	Organic matter 37.60
Uric acid	0.60	
Hippuric acid	0.35	
Creatinin	0.65	
Extractives	8.00	
Sodium chloride	8.00	Inorganic matter, 12.40
Phosphoric acid	2.00	
Sulphuric acid	1.25	
Lime (CaO)	0.25	
Magnesia (MgO)	0.30	
Potash (K_2O) and soda (Na_2O)	0.60	
Total	1000.00	

When carbonates occur in the urine it is alkaline.

8. *Osmosis:* "If two different liquids are separated from each other by a porous partition, a current sets in from each liquid to the other. The strength of these currents depends on the facility with which the liquids are imbibed by the partition and the tendency the two fluids have to mix with each other; the fluid which soaks most rapidly into the partition—*i. e.* that which wets it most readily—passes through it most rapidly. If a bladder be filled with syrup and immersed in water, the water will pass into the bladder more rapidly than the syrup passes out, and may so far raise the pressure in the interior of the bladder as to burst it. The water is said to pass into the bladder by *endosmosis*, and the syrup to pass out by *exosmosis.*"

HISTOLOGY.

1. See Cunningham's "Anatomy" (1909), page 71; or Gray's "Anatomy" (1910), pages 37 and 38.

2. See Cunningham's "Anatomy" (1909), page 1139; or Gray's "Anatomy" (1910), page 1352.

3. (1) Red corpuscles, about 5,000,000 to the cubic millimeter. (2) White corpuscles, about 7,000 to 10,000 per cubic millimeter; (of these, there are: Small mononuclears, about 20 per cent.; large mononuclears, about 8 per cent.; polynuclears, about 70 per cent.; and eosinophiles, about 2 per cent.). (3) Platelets, about 400,000 to the cubic millimeter.

4. A lobule of the liver is about 1-20 to 1-12 inch in diameter. It has a darkish red center and a lighter circumference. The center is occupied by an intralobular vein which collects the blood from the capillaries of the lobule, and flows into the sublobular vein, which latter opens into the hepatic vein. Around the lobules are the interlobular veins; these are branches of the portal system; capillaries passing from the circumference to the center of the lobule connect the interlobular and intralobular veins. Between the network of capillaries in the lobule the hepatic cells are packed.

PATHOLOGY.

1. See French's "Practice of Medicine" (1910), pages 518 and 521; or Osler's "Practice of Medicine" (1909), pages 722 and 726.

2. See French's "Practice of Medicine" (1910), page 154; or Osler's "Practice of Medicine" (1909), page 170.

3. See French's "Practice of Medicine" (1910), page 843; or Osler's "Practice of Medicine" (1909), page 557.
4. See Rose and Carless' "Surgery" (1908), page 570; or Da Costa's "Surgery" (1908), page 440.

CHEMISTRY.

1. *To determine the positive pole in a galvanic battery:* Use the battery for the electrolysis of (acidulated) water; oxygen is given off at the positive pole.
2. By the *equivalence of an atom* is meant its saturating power as compared with that of an atom of hydrogen.
3. Chlorine is a gaseous, halogen element; symbol is Cl; atomic weight, 35.5; molecular weight, 71; specific gravity, 2.45.
4. The antidotes for poisoning with the alkaline caustics are dilute vinegar, milk, neutral oils.
5. *Trommer's test* is a copper reduction test for sugar in the urine. Add to the suspected urine about one-eighth of its bulk of 10 per cent. solution of NaOH or KOH, then two or three drops of 10 per cent. solution of $CuSO_4$, and heat to boiling. In the presence of sugar a yellow precipitate is formed, which becomes darker and reddish on boiling.
6. *The Pettenkofer* test is used for the detection of biliary acids. *Method:* "Add to the pure aqueous solution of the acids or their salts one or two drops of a solution of cane sugar (1 to 4); agitate; float this liquid carefully upon concentrated H_2SO_4; a turbid zone is formed at the junction of the two layers, soon replaced by a deep purple zone which gradually extends upward and downward." (Witthaus' *Essentials of Chemistry.*)
7. Urea is formed in the liver chiefly, also in other organs; the daily excretion of urea is about 500 grains.
8. Alkaloids are basic, nitrogenous, organic substances, alkaline in reaction, generally of bitter taste, and capable of combining with acids to form salts in the same way that ammonia does.
A *general chemical antidote for alkaloids* is tannic acid in solution.
9. *Ptomaines* are basic, nitrogenous organic substances produced from protein material by the bacteria which cause putrefaction. *Examples:* Putrescin, cadaverin, neuridin. Some ptomaines are poisonous, and some are not.

DIAGNOSIS.

1.

ACUTE MILIARY TUBERCULOSIS.	TYPHOID FEVER.
Temperature curve is irregular.	Temperature curve is characteristic.
Diarrhea is not common.	Diarrhea is common.
Roseolar eruption not common.	Roseolar eruption is generally present.
No typhoid bacilli in blood, urine or feces.	Typhoid bacilli in blood, urine, and feces.
Tubercles may be found in the choroid.	No tubercles in the choroid.
Pulse and respiration are usually much more rapid.	Pulse and respiration rapid.
Epistaxis is rare.	Epistaxis is common.

2. See French's "Practice of Medicine" (1910), pages 1068 and 348; or Osler's "Practice of Medicine" (1909), pages 915 and 302.
3. See French's "Practice of Medicine" (1910), page 765; or Osler's "Practice of Medicine" (1909), page 473.
4. See French's "Practice of Medicine" (1910), page 927; or Osler's "Practice of Medicine" (1909), page 697.
5. See French's "Practice of Medicine" (1910), page 965; or Osler's "Practice of Medicine" (1909), page 414.
6. See French's "Practice of Medicine" (1910), page 853; or Osler's "Practice of Medicine" (1909), page 564.
7. See French's "Practice of Medicine" (1910), page 784; or Osler's "Practice of Medicine" (1909), page 492.
8. See French's "Practice of Medicine" (1910), page 380; or Osler's "Practice of Medicine" (1909), page 336.

MATERIA MEDICA AND THERAPEUTICS.

1. ANTIDOTES. For *oxalic acid*, chalk or lime; for *corrosive sublimate*, white of egg, or milk; for *arsenic*, freshly prepared solution of ferric hydroxide; for *gelsemium*, ammonia, strychnine, or digitalis; for *copper sulphate*, potassium ferrocyanide; for *iodine*, starch.
2. *Physiological effects of ether inhalations:* "Ether when inhaled produces at first faucial irritation, a sense of strangulation and cough; then a stage of excitement (cerebral intoxication), in which the face is flushed and the respiration and pulse are accelerated. A tetanic convulsive stage generally follows, the face being cyanosed, the muscles rigid, and the respiration stertorous. This soon subsides, and complete insensibility is established, the muscles being then relaxed, the reflexes abolished, and the cerebral functions suspended, the lower centers in the medulla carrying on the processes of respiration and circulation. If the inhalation be continued, these also become paralyzed, death usually resulting from slow paralysis of respiration, the heart pulsating long after breathing has ceased. If the inhalation be discontinued before the lower centers are affected, the patient gradually emerges from the condition of insensibility, and, as the narcosis subsides, vomiting is usually experienced." (Potter's *Materia Medica*, etc.).
3. *Incompatibles of silver:* Alkalies, and their carbonates; alkaloids; solutions of arsenic and tannin; most of the mineral acids and their salts; all bromides, chlorides, iodides, and phosphates; practically, all drugs except opium and hyoscyamus.
4. *Two vesicants:* Cantharides, and iodine; *two irritants:* Ammonia and silver nitrate; *two escharotics:* Nitric acid and phenol; *two rubefacients:* Mustard and menthol; *two diaphoretics*: Alcohol and nitrous ether; *two diuretics*: Potassium acetate and juniper; *two anthelmintics!* Pelletierine and santonin; *two cardiac depressants:* Aconite and antimony.
5. *Physiological effect of digitalis:* It is a gastro-intestinal irritant, it slows the rate of the heart, prolongs diastole, increases the force of the heart, it contracts the blood-vessels and causes a rise in blood-pressure, it also acts as a diuretic.
6. *Therapeutic uses of aconite:* For fevers, some inflammatory conditions, in high arterial tension, in nervous palpitation of the heart, and congestive dysmenorrhea; also externally for neuralgia, pruritis, herpes, chilblains, etc.
7. *Emmenagogues* are supposed to act on a non-gravid uterus; *ecbolics* are only used in pregnancy. *Emmenagogues* if given in too large a dose are apt to have *ecbolic* properties.
8. Two ounces = 960 grains; a 3 per cent. solution will therefore contain 28.8 grains.

PRACTICE OF MEDICINE.

1. See French's "Practice of Medicine" (1910), pages 316 and 318; or Osler's "Practice of Medicine" (1909), pages 132 and 131.
2. See French's "Practice of Medicine" (1910), pages 577, 578, and 581; or Osler's "Practice of Medicine" (1909), pages 785, 786, and 787.
3. See French's "Practice of Medicine" (1910), page 154; or Osler's "Practice of Medicine" (1909), page 170.
4. In *neuritis* the pain is continuous, is always worse after use of the nerve, and does not vary in situation; painful points are present; the nerve trunk is tender, and the pain can be increased proportionately with pressure; it is not limited to sensory nerves, and trophic disturbances, wasting, and alterations in the electrical reactions are very apt to appear.
In *neuralgia* the pain is paroxysmal and intermittent; it is independent of the use of the nerve; it may vary in situation; painful points are not often present; the nerve trunk is not particularly tender, and a light pressure along the nerve trunk may cause as much pain as a heavy pressure; neuralgia only affects sensory nerves, and wasting and trophic disturbances only rarely occur.
5. In *diphtheria* the onset is more gradual; the temperature rises to about 101° to 103° F.; the tonsils are not much enlarged; there is an exudate of a thick, grayish membrane which is very adherent, is removed only with difficulty, and leaves a bleeding surface; this membrane soon reforms and may be found on the fauces and pharynx as well as on the tonsils; in the exudate the Klebs-Loeffler bacilli may be found. In *follicular tonsillitis* the onset is more sudden; the temperature may be a little higher than that of diphtheria; there is no membrane, but the tonsils are red and swollen, and in the crypts are seen white, cheesy spots or plugs, which consist of broken-down epithelium, and are easily brushed away; Klebs-Loeffler bacilli are never found.
6.

EXANTHEM.	INCUBATION PERIOD.	ERUPTION PERIOD.
Cerebro spinal meningitis.	Unknown.	2nd to 4th day.
Erysipelas.	Few hours to 3 or 4 days.	First day.
Measles.	10 to 12 days.	Fourth day.

EXANTHEM.	INCUBATION PERIOD.	ERUPTION PERIOD.
Rotheln.	7 to 17 days.	Second day.
Scarlet fever.	1 to 21 days.	1st or 2nd day.
Typhoid fever.	5 to 30 days.	7th to 10th day.
Typhus fever.	4 to 12 days.	3rd to 7th day.
Varicella.	4 to 14 days.	First day.
Variola.	8 to 14 days.	About fourth day.

7. See French's "Practice of Medicine" (1910), page 101; or Osler's "Practice of Medicine" (1909), page 93.

8. See below, NERVOUS DISEASES, Question 1.

DISEASES OF CHILDREN.

1. See Rose and Carless' "Surgery" (1908), page 872; or Da Costa's "Surgery" (1908), pages 137, 151, and 142.

2. See Rose and Carless' "Surgery" (1908), pages 124 to 128; or Da Costa's "Surgery" (1908), pages 204 to 209.

3. See French's "Practice of Medicine" (1910), pages 567, 576, and 619; or Osler's "Practice of Medicine" (1909), pages 775, 785, and 824.

4. See French's "Practice of Medicine" (1910), pages 711, 713, and 171; or Osler's "Practice of Medicine" (1909), pages 649, 651, and 188.

5. The capacity of the stomach of an infant one day old is about one ounce.

6. See French's "Practice of Medicine" (1910), page 798; or Osler's "Practice of Medicine" (1909), page 504.

7. See French's "Practice of Medicine" (1910), pages 194 and 195; or Osler's "Practice of Medicine" (1909), page 207.

8. See French's "Practice of Medicine" (1910), page 188; or Osler's "Practice of Medicine" (1909), page 202.

NERVOUS DISEASES.

1. See French's "Practice of Medicine" (1910), pages 25, 27, 1107, and 1115; or Osler's "Practice of Medicine" (1909), pages 966 and 977.

2. (*a*) A disease with morbid lesion in the anterior columns of the cord: Progressive muscular atrophy; (*b*) in the lateral columns: Spastic spinal paralysis; (*c*) in the posterior columns: Tabes dorsalis.

3. See French's "Practice of Medicine" (1910), page 1080; or Osler's "Practice of Medicine" (1909), page 904.

4. See French's "Practice of Medicine" (1910), pages 142 and 146; or Osler's "Practice of Medicine" (1909), pages 160 and 163.

SURGERY.

1. Scarpa's triangle is bounded *above* by Poupart's ligament, *externally* by the Sartorius, and *internally* by the inner margin of the Adductor longus; its *apex* is formed by the junction of the Adductor longus and Sartorius. The *floor* is formed, from without inward, by the Iliacus, Psoas, Pectineus, Adductor brevis, and Adductor longus. *Contents:* The femoral vessels pass from about the center of the base to the apex, the artery being on the outer side of the vein; the anterior crural nerve lies to the outer side of the femoral artery; the external cutaneous nerve is still further external, lying in the outer corner of the space; just to the outer side of the femoral artery, and in the sheath with it, is the crural branch of the genito-crural nerve.

For ligation of superficial femoral artery, see Rose and Carless' "Surgery" (1908), page 340; or Da Costa's "Surgery" (1908), page 423.

2. The arteries to be tied are: The radial, ulnar, anterior interosseous, and posterior interosseous. The radial and ulnar are continuations of the brachial; the anterior and posterior interosseous are branches of the interosseous, which is a branch of the ulnar artery.

3. THE ELBOW. "The more important normal landmarks are: (*a*) The two condyles of the humerus and the tip of the olecranon process form an equilateral triangle when the arm is flexed to a right angle. When the arm is extended they lie in a straight line. (*b*) The head of the radius can be felt to rotate below the external condyle of the humerus. (*c*) An angle is formed by the radius and ulna with the humerus when the hand and forearm are held in a supinated position, which is known as the *carrying angle*.

If the two condyles of the humerus lie in their normal relation to the olecranon process as determined by palpation, this will exclude a dislocation of both bones of the forearm, a fracture of either condyle or a fracture of the olecranon process.

If the head of the radius can be felt to rotate in its normal position this will exclude a fracture of the neck or head of the radius and a dislocation of the radius." (Eisendrath's *Surgical Diagnosis.*)

4. See Rose and Carless' "Surgery" (1908), page 443; or Da Costa's "Surgery" (1908), page 661.

5. *Structures divided in the operation for strangulated femoral hernia* are: Skin, superficial fascia, cribriform fascia, crural sheath, septum crurale, subserous areolar tissue, and peritoneum.

6. *Division of the radial nerve* would be followed by: Loss or impairment of sensation in the dorsal aspect of thumb, index finger, and radial side of middle finger as far as the second phalanx.

7. See French's "Practice of Medicine" (1910), pages 885 and 882; or Osler's "Practice of Medicine" (1909), pages 586 and 582.

In *fecal impaction*, there is a history of long continued and increasing constipation, feeling of languor and depression, anorexia; the abdomen becomes distended gradually, and the symptoms develop slowly; pain comes on gradually, and later becomes continuous; there is usually a tumor in sigmoid flexure or cecum, it is doughy and firm; constipation is absolute.

8. The chief *surgical diseases of the groin* are: Hernia (inguinal, femoral, and obturator), aneurysms, tumors, abscesses (psoas, glandular, and from hip disease), cysts, ulcers, sinuses, enlarged glands, undescended testicle, prolapsed ovary.

OBSTETRICS.

1. See Williams' "Obstetrics" (1909), page 102; or Hirst's "Obstetrics" (1909), page 110.

2. The connection between ovulation and menstruation is not yet definitely settled, but the two functions seem to be closely associated. It has been held that ovulation is dependent upon menstruation; also that menstruation is dependent upon ovulation; it has also been proved that each may occur without the other, and it is possible that they are both dependent upon some common (and as yet unknown) cause.

3. *Differential diagnosis.—Pregnancy:* The tumor is hard and does not fluctuate, is situated in the median line, and may give fetal heart sounds and movements; the cervix is soft, and the other signs of pregnancy are present. The rate of growth of the tumor, and the general condition of the patient's health may also help in arriving at a diagnosis.

Ascites: Absence of the signs of pregnancy; the abdomen is distended, but the shape varies with the position of the patient; on lying down there is bulging at the sides; the tumor fluctuates, and percussion shows dullness in the flanks, with resonance in the median line, but the dullness varies with the position of the patient.

4. The *characteristic symptom* of placenta prævia is: Sudden hemorrhage (accompanied by syncope, vertigo, restlessness, and feeble pulse). *Treatment:* Stop the hemorrhage by a vaginal tampon; this must be tight and thorough. *Accouchement forcé* is indicated; this consists of dilatation of cervix, version, and immediate extraction of the child.

5. See Williams' "Obstetrics" (1909), page 298; or Hirst's "Obstetrics" (1909), pages 343 and 435.

6. See Williams' "Obstetrics" (1909), page 360; or Hirst's "Obstetrics" (1909), page 566.

7. See Williams' "Obstetrics" (1909), page 846; or Hirst's "Obstetrics" (1909), page 939.

8. See Williams' "Obstetrics" (1909), page 350; or Hirst's "Obstetrics" (1909), page 949.

The cause of icterus of the new-born is not known. It is found most often in premature and weakly infants, and in those born in maternity hospitals. The following theories have been held as to its etiology: "(1) *Obstruction to the outflow of bile* by (*a*) plugs of mucus in the common bile duct; (*b*) partial blocking of the bile ducts by desquamated epithelium, the result of hyperemia and catarrh of the ducts following on the changes in the circulation which take place at birth; (*c*) congenital narrowing of the bile ducts; (d) inability of the ducts to carry off the secretion of bile, which is considerable at first; and (*e*) delayed ligature of the cord. (2) *Pressure on the ducts from without* by (*a*) the portal and hepatic veins becoming distended in consequence of the changes in the circulation following birth; (*b*) swelling and edema of Glisson's capsule, the result of engorgement of the umbilical and portal veins—hence the jaundice is hepatogenous. (3) Closure of the umbilical vein, which leads to such a lowering of blood-pressure in the capillaries of the liver that reabsorption of bile takes place. (4) The ductus venosus, which should close from the second to the fifth day after birth, remains open longer than this, and thereby allows some portal blood, which contains bile, to pass through it and enter the inferior vena cava."—(From *Aids to Diseases of Children*)

9. See Williams' "Obstetrics" (1909), pages 435 and 437; or Hirst's "Obstetrics" (1909), pages 827 and 830.

GYNECOLOGY.

1. See Rose and Carless' "Surgery" (1908), page 1283.

2. *Vaginitis* is a condition of inflammation of the vagina. It is characterized by redness, swelling, pain, heat, irritation, and increased secretion. There may be frequent and painful urination. *Treatment* consists in rest, cleanliness, douches, the application of soothing lotions, and removal of any cause; salines and anodynes are also indicated.

3. *Cystocele* is a hernia of part of the bladder into the vagina, covered by the mucous membrane of the anterior vaginal wall. *Symptoms:* A dragging sensation in the lower pelvic cavity; a feeling of distention at the vulva; loss of power in urination; tumor of anterior vaginal wall more apparent on straining; prolapse of uterus.

For radical cure of cystocele: "The patient is placed in dorsal position. The posterior vaginal wall is kept out of the way with a weighted speculum. The cervix is drawn down with a bullet-forceps. With a pair of tenacula the sides of the prominence are drawn together in the median line in order to see how much of the wall is redundant and these points are marked with small nicks. Next, the whole surface is put on the stretch between four pairs of forceps —one at each of the sidemarks, one near the cervix, and one at the transverse ridge at the inner end of the urethra. With a pair of scissors curved on the flat, a strip about ¼ inch wide is cut out of the mucous membrane. Similar strips are removed on both sides until an oval is denuded. Finally a running suture of chromicized catgut is passed under the whole pared surface, uniting the edges from side to side." If necessary, a perineorrhaphy should be done at the same time.

4. *Operation for rectocele.* The operation of posterior colporrhaphy is thus described by Sutton and Giles: "The patient is secured in the lithotomy position, and the vagina thoroughly exposed with retractors. An elliptical incision, one end of the major axis being close to the cervix, the other near the vulvar orifice, is made in the mucous membrane of the posterior vaginal wall, taking care not to cut deeper than the recto-vaginal septum, lest the bowel be opened. The vaginal mucous membrane is then cautiously dissected off; the amount to be removed is estimated by the laxity of the parts and the degree of narrowing which the operator regards as necessary to meet the needs of the case. After removing the vaginal wall and securing the bleeding vessels the cut edges of the mucous membrane are brought into apposition by a continuous silk suture on interrupted suture of silk-worm-gut, or such other material as the operator thinks well to employ. The patient is kept in bed for at least two weeks; her bowels are regulated, and the bladder should not be allowed to become overdistended. The sutures should be removed in about ten days."

5. Intrauterine applications are not, as a rule, in much favor. After a curettage, or miscarriage, application of iodine or carbolic solution may be beneficial in preventing sapremia or sepsis; and in severe uterine hemorrhage application of adrenalin chloride may be used.

The danger in intrauterine application lies in the fact that the cavity of the uterus communicates by the Fallopian tubes with the general peritoneal sac, and that peritonitis and death have resulted from intrauterine injection.

6. *Prolapse of ovary:* "Downward displacement without displacement of the tubes and uterus may result from prolonged congestion, inflammation, subinvolution, elongation, and stretching of the ligaments, or violent strain. The symptoms are constant with severe pain, which is increased by movement and at the menstrual period, nausea and indigestion, headache, and nervous disturbances. Bimanual examination reveals enlargement, tenderness, and the abnormal position of the ovary. In uncomplicated cases the ovary may be restored to its proper position by directing the patient to assume the knee-chest posture for ten minutes two or three times daily, or the infundibulo pelvic ligaments may be shortened through an abdominal incision. Pelvic congestion will require the use of saline laxatives, hot vaginal douches, the application of iodine to the cervix and vaginal vaults, and the use of glycerin tampons. Diseased ovaries should be removed and uterine displacements should be corrected."—(Gould and Pyle's *Pocket Cyclopedia.*)

7. *Menorrhagia* is a condition characterized by excessive loss of blood at the menstrual periods.

Metrorrhagia is a hemorrhage from the uterus at other than the menstrual periods.

Metrorrhea is any discharge from the uterus, such as mucus, pus.

Amenorrhea is absence of menstruation during the period of sexual activity.

8. *Treatment of menorrhagia:* Remove the cause, if possible; treat abnormal conditions that are present; vaginal douches, tampons, and curettage have been recommended; also ergot, hamamelis, hydrastis, and viburnum prunifolium; rest in bed is necessary. Intrauterine applications of astringents or of adrenalin have been used.

Treatment of amenorrhea: This consists in (1) Removing the cause, if possible; (2) general treatment by means of proper hygiene, rest, diet, bathing, attention to the bowels, exercise, etc.; (3) drugs reputed to be emmenagogues such as iron, manganese, aloes, strychnine, apiol, oxalic acid, savine, rue, and tansy.

EYE AND EAR.

1. For *otitis media*, see Rose and Carless' "Surgery" (1908), pages 880, etc.

Indications for opening the ear drum Undue distention in otitis media, hyperemia and infiltration of the membrana tympani, or for purposes of exploration.

Landmarks of ear-drum: (1) The short process of the malleus; (2) the manubrium or long process of the malleolus and umbo; (3) the light spot.

Point for paracentesis: In the posterior and lower portion of the tympanic membrane.

Dangers of paracentesis: The point of the knife may strike the stapes or the long process of the incus, and the hearing may be damaged; sepsis.

2. See Rose and Carless' "Surgery" (1908), page 885.

3. *Glaucoma* is a diseased condition of the eye, produced by increased intraocular pressure, and resulting in excavation and atrophy of the optic disc, and blindness. It is due to increase of the contents of the eye, hypersecretion, retention, old age, gout, rheumatism, nephritis. *Symptoms:* Visual disturbances, increased ocular tension, hazy and anesthetic cornea, sluggish and dilated pupil, shallow anterior chamber, ciliary neuralgia, cupping of optic disc, blindness. *Treatment:* Myotics, such as eserine or pilocarpine; massage of the eyeball; mydriatics are contraindicated; operative treatment may include paracentesis, iridectomy, or sclerotomy. *Prognosis:* This is unfavorable; unless proper treatment is at once instituted blindness results.

	GLAUCOMA.	IRITIS.
Age	Over forty.	Any.
Tension	Plus.	Normal.
Congestion	General, especially scleral.	General, especially circumcorneal.
Cornea	Cloudy and steamy surface.	Cloudy.
Anterior chamber.	Shallow.	Unchanged.
Pupil	Dilated, oval.	Contracted, synechiæ.
Pain	Severe, continuous.	Especially at night.
Vision	Much reduced.	Somewhat reduced.
Treatment	Eserine, pilocarpine, iridectomy.	Atropine.

(From Alling and Griffin's *Diseases of the Eye and Ear.)*

4. OPHTHALMIA NEONATORUM. *Causes:* The gonococcus or some other pyogenic microorganism; the secretions of the mother contain the infecting agent, and transmission may occur directly during parturition, or indirectly by the fingers of physician or nurse, cloths, instruments, etc. *Symptoms:* Swollen eyelids, with copious purulent discharge; ulceration of the cornea may ensue. *Complications:* Corneal ulceration, perforation, and panophthalmitis. *Prophylaxis:* Whenever there is the possibility of infection, or in every case, wash the eyelids of the newborn child with clean warm water, and drop on the cornea of such eye one drop of a 1 per cent. solution of nitrate of silver, immediately after birth. *Treatment:* Wash the eyes carefully every half hour with a saturated solution of boric acid; pus must not be allowed to accumulate. Two drops of a 2 per cent. solution of nitrate of silver must also be dropped on to the cornea every night and morning. The eyes must be covered with a light, cold, wet compress. The patient must be isolated, and all cloths and compresses used must be burnt.

LEGAL MEDICINE.

1. *Conditions warranting the induction of premature labor:* (1) Certain pelvic deformities, (2) placenta prævia, (3) pernicious anemia, (4) toxemia of pregnancy, (5) habitual death of the fetus toward the end of pregnancy,

(6) hydatidiform mole, (7) habitually large fetal head.

The methods that may be employed are: Partial dilatation of the cervix and the introduction within the cervix (and vagina) of a tamponade of sterile gauze; (2) dilatation of the cervix; (3) puncturing the membranes; (4) introduction of a soft rubber bougie into the uterus; (5) intrauterine injection of glycerin, water, or some other fluid.

2, 3, and 4. The evidences of poisoning depend upon (1) the symptoms; (2) the post-mortem appearances; (3) the results of chemical analysis, and (4) circumstantial evidence. The general practitioner can report on (1) and (2); he had better leave (3) to an expert chemist. But to aid this latter he should preserve certain parts of the body for analysis: "The alimentary canal from the cardia to the middle of the rectum, *unopened,* and the contents enclosed by ligatures at the esophagus, duodenum, and lower end of gut; the liver, including the gall-gladder; one kidney; the spleen; a piece of muscular tissue; the brain, and any urine which may remain in the bladder. Any suspected food articles, and any obtainable vomited matter, are to be also preserved. They are to be placed in *clean* and *new* glass jars, closed with glass or cork covers or stoppers. Jars with metallic caps should never be used. Tapes or cords should be tied about the jar and cap, to which they should be attached by sealing wax bearing impressions of a seal, in such a manner that access can only be had to the interior after breaking the seals or cutting the tapes or cords. Great care must be exercised that no sealing wax can get into the jars. Each portion should be placed in a jar by itself." (Witthaus.)

2. In *poisoning by arsenic: Symptoms:* "In acute cases the symptoms usually begin in from twenty to forty-five minutes. Nausea and faintness. Violent, burning pain in the stomach, which becomes more and more intense, and increases on pressure. Persisting and distressing vomiting of matters, sometimes brown or gray, or streaked with blood, or green (Paris green). Purging. More or less severe cramps in the lower extremities."

In *chronic cases:* "Inflammation of the conjunctivæ, with intolerance of light. Irritation of the skin, accompanied by an eruption (eczema arsenicale). Local paralyses. Great weakness and emaciation. Exfoliation of the cuticle and falling out of the hair." (Witthaus.)

Post-mortem appearances: "These are confined to the stomach and intestines. The stomach is inflamed, whether As has been taken by the mouth or by other channels of absorption. The mucous surface is coated with a layer of mucus, tinged with blood or bile, and sometimes containing white crystals of As_2O_3 or green particles of Paris green. The color of the mucous membrane is brownish red, interspersed with darker streaks or patches between the rugæ. The small intestines are sometimes inflamed throughout their length but more usually the inflammation is limited to the duodenum (Witthaus' *Essentials.*)

3. *Symptoms of poisoning by morphine:* "At first there is usually a period of excitation, marked by restlessness, great physical activity, loquacity, and hallucinations. The patient then becomes weary, dull, and drowsy; he yields to the desire for sleep, from which at first he may be roused. The lips are livid, the face pale, the pupils contracted, and the surface bathed in perspiration. The condition of somnolence rapidly passes into narcosis. The patient cannot be roused, and lies motionless and senseless, with completely relaxed muscles. The pulse, at first full and strong, becomes feeble, slow, irregular, and easily compressible; the respiration slow, shallow, stertorous, and accompanied by mucous râles. The patient rapidly becomes comatose, and, in fatal cases, dies in from forty-five minutes to fifty-six hours, usually in from twelve to eighteen hours. In cases of recovery after the stage of narcosis the pulse and respiration gradually return to the normal, and the condition of coma passes into one of deep sleep, lasting twenty-four to thirty-six hours." (Witthaus.)

Post-mortem appearances: The brain may be congested, the cerebrospinal fluid increased in amount, the urine in the bladder may contain morphine or some of its oxidation products, the intestine may be ulcerated.

4. The *symptoms of poisoning by strychnine* are "a sense of suffocation, thirst, tetanic spasms, usually opisthotonos, sometimes emprosthotonos, occasionally vomiting, contraction of the pupils during the spasms, and death, either by asphyxia during a paroxysm, or by exhaustion during a remission. The symptoms appear in from a few minutes to an hour after taking the poison, usually in less than twenty minutes; and death in from five minutes to six hours, usually within two hours." (Witthaus' *Essentials.*)

Post-mortem appearances: There is frequently well marked rigidity of the muscles, with incurving of the soles, and the hands may be clenched, but often the muscles are relaxed immediately after death and become rigid later.

Medical Items.

Contagious Diseases, Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ended November 11, 1911:

	Cases	Deaths
Tuberculosis Pulmonalis	347	139
Diphtheria	248	12
Measles	116	4
Scarlet Fever	122	4
Smallpox	—	—
Varicella	129	—
Typhoid Fever	92	14
Whooping Cough	36	2
Cerebrospinal Meningitis	3	—
Malarial Fever	—	
Totals	1093	175

Typhoid Fever Ushered in with Renal Manifestations.—Lesieur reports the case of a 14-year-old girl in whom typhoid fever began suddenly with the manifestations of inflammation of the kidneys, including renal pain, cephalalgia, hematuria, and hypertrophy of the left kidney.—*Bulletin et Memoires de la Société Médicale des Hôpitaux.*

Health Reports.—The following cases of and deaths from smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine Hospital Service, during the week ended November 10, 1911:

Places	Date	Cases	Deaths
CHOLERA			
India: Madras	Sept. 23–20	6	3
Indo-China: Saigon	Sept. 10–17	5	5
Java: Batavia	Sept. 16–23	18	6
Russia: Astrakhan	Sept. 13–30	24	11
Don	Sept. 13–30	1	1
Kuban	Sept. 13–30	23	15
Rostov on Don	Sept. 13–30	7	5
Saratov	Sept. 13–30	22	9
Simbrisk	Sept. 13–30	3	5
Ufa	Sept. 13–30	2	..
Servia: Belgrade	Oct. 7–14	2	1

TRAUMATIC LESIONS OF THE EAR.*

BY GORHAM BACON, M.D.,

NEW YORK.

PROFESSOR OF OTOLOGY, COLLEGE OF PHYSICIANS AND SURGEONS, COLUMBIA UNIVERSITY.

IT would be impossible in the short time at my disposal this evening to enter into a discussion of the many injuries that may involve the auditory apparatus, so that I shall refer briefly to the more important lesions, and report a few of the more interesting cases that have come under my observation.

While a slight blow on the ear may cause a serious lesion of the labyrinth and nervous apparatus, leading to permanent deafness, a more violent blow may cause simply a rupture of the drumhead, which will heal in a short time, leaving the hearing but little, if any, impaired. In other words, if the injury is such that the drumhead is ruptured we are much less likely to have a serious involvement of the inner ear. A slight blow on the ear, causing a sudden condensation of air in the external ear, may so expend itself upon the drumhead and ossicles that the stapes is suddenly forced inwards, increasing the intralabyrinthine pressure, and in this way a serious condition of affairs follows, so that permanent deafness and tinnitus are likely to result.

Of the traumatic lesions affecting the membrana tympani, another frequent cause, besides blows and falls, is the bad habit on the part of some individuals of using hairpins, toothpicks, etc., to scratch the auditory canal on account of itching, and accidentally such instruments are pushed in too far.

A patient came to me some years ago with a serious rupture of the membrana. He had just sharpened a pencil, and while trying to scratch the auditory canal with the point, to relieve the itching, some one accidentally pushed his elbow and the point was driven through the drumhead.

A number of years ago I reported a case of injury to the drumhead which was caused by the twig of a branch entering the auditory canal of a man who was walking through a forest. Too forcible inflation of the ear by Politzer's method or the rapid rarefaction of air by means of Siegle's otoscope may produce a rupture.

If the Eustachian tube is obstructed so that air in the middle ear cannot easily escape, when condensation of air in the external auditory canal follows a blow, we are likely to have a rupture of the membrane. Changes in the drumhead, such as atrophy, chalky deposits, etc., favor a rupture.

Ruptures are frequently caused by inexperienced practitioners attempting to remove foreign bodies from the canal without proper illumination. One case which came under my observation was that of a man who was brought to the infirmary with a severe laceration of the canal and middle ear, due to an attempt to remove a supposed foreign body by means of forceps. In addition to a severe laceration of the canal, the drumhead had been destroyed and the ossicles removed. During the summer months diving in salt water occasionally causes a rupture, besides permanently impairing the hearing in a great many instances. Sea bathers should always be advised to protect their ears, not only on account of the liability of such an accident, but also owing to the fact that those who constantly dive and swim under water, when young, are frequently deaf later in life, and such deafness is due to thickening of the drumhead, anchylosis of the ossicles and the formation of exostoses in the external auditory canal.

The membrana may also be injured by a syringe with a long and fine point in the hands of an inexperienced person. In snow-balling, a rupture occasionally follows. By the introduction of a bougie through the nose and Eustachian tube the point may be pushed through the membrana, and when, a few years ago, electrolysis was advocated so strenuously on the part of some writers, such an accident was occasionally reported.

Another cause of rupture is fracture at the base of the skull, giving rise to copious bleeding from the auditory canal, and the escape of cerebrospinal fluid if the labyrinth is involved.

When a rupture follows the sudden condensation or rarefaction of air in the external auditory canal, it may be due not only to blows or falls, but also to loud explosions, the firing of cannon. It occurs in caisson workers and aviators, especially if there is some obstruction in the Eustachian tube.

Injuries of the canal and membrane are occasionally due to the instillation of hot fluids, the use of hot vapors, and of drops for earache, suggested by anxious friends. When St. Jacob's oil was in favor a patient came under my care with a serious middle ear inflammation due to its use, it having been suggested as a good remedy to put into the ear for earache.

Injuries of the auricle occur, such as contusions, stab-wounds, etc., which, as a rule, are more frequently seen by the general surgeon, and in boxers othæmatoma of the auricle is of frequent occurrence, and causes marked deformity if not properly treated. A number of years ago I reported a case of gunshot wound of the mastoid.

Symptoms.—When a rupture occurs from a direct injury, *i. e.*, by the introduction of an instrument in the auditory canal, much depends on the size and nature of the instrument. The canal may be lacerated, and the rupture is generally found in the anterior half of the membrane. Wet or dried blood is observed around the margins of the rup-

*Read at a meeting of the Practitioners' Society, October 13, 1911.

ture as well as in the canal. The wound may heal, leaving but little deafness, but usually severe reaction follows, and inflammation and suppuration lead to more or less permanent deafness.

The symptoms usually complained of are a loud report in the affected ear, followed by severe pain, dizziness, tinnitus, faintness, vertigo, and hemorrhage. As a result of a direct injury the stapes may be dislocated, causing serious dizziness, tinnitus, and permanent deafness, and following suppurative inflammation, permanent openings in the membrana may remain, or adhesions may follow, and the ossicles may be anchylosed, leading to permanent deafness.

In ruptures due to the sudden condensation or rarefaction of air the symptoms usually are not so severe. At the time the patient feels great pain and hears a loud report. He is seized with dizziness, and frequently reels and complains of tinnitus. When the membrana is examined, fresh or dried blood is found around the margins of the rupture, unmistakable evidences of traumatism and coagula may be found in the canal. The impairment of hearing is less marked in these cases than in those due to direct injury, and when the patient is very deaf it is generally due to involvement of the labyrinth. When the membrana is ruptured, the force of the blow is felt on the membrana, and the labyrinth usually escapes.

Politzer says, "if, on the other hand, the membrane remains intact, the greater part of the force of the blow is exerted upon the labyrinth, inasmuch as the chain of ossicles, suddenly forced inwards, causes a concussion and paralysis of the endings of the auditory nerve: as a consequence of this severe deafness and continuous noises remain. According to the author's observations the prognosis of these cases is always unfavorable."

Some years ago a child was brought to my office who did not talk, and from an examination proved to be a deafmute. On close questioning I finally elicited the information that, when a baby, she had fallen, striking on her head.

A traumatic rupture generally closes in from three or four days to two weeks, if left to nature, and all local applications are omitted. Syringing the ear, and the use of all drops, should be carefully avoided. The canal may be wiped out carefully with cotton on an applicator moistened with a disinfectant, and afterwards dried. Then a strip of sterile gauze or cotton should be reinserted in the canal. After this the healing should be left to nature. When the labyrinth has not been affected, and the traumatism of the membrane has been due to a sudden condensation or rarefaction of air in the external auditory canal, closure of the membrane usually occurs. According to Politzer, "cicatrization often begins in the mucous membrane layer, inasmuch as, several days after the rupture, a grayish-yellow membrane forms over the opening from within, while the edges of the tear in the cutis are still visible for some time." Suppuration of the middle ear may result from such ruptures, but less frequently than in cases due to direct injury.

The *prognosis* of cases of deafness due to slight concussions of the labyrinth is usually favorable, although a constant tinnitus may remain after the hearing has been restored. On the other hand, violent concussion of the labyrinth from explosions, etc., is usually followed by marked deafness, which is apt to be permanent, and a distressing tinnitus. Patients are apt to complain of a feeling of fulness in the head, as well as dizziness, and marked hyperesthesia acustica. They are frequently very nervous and at times hysterical.

Serious complications, not only involving the middle ear and labyrinth, but also the meninges and brain, have been reported from attempts made to remove foreign bodies from the external auditory canal, so that it is a most unwise procedure for one inexperienced in the use of the speculum and head mirror to undertake to remove a foreign body from the canal.

Many cases of severe traumatism, according to my observation, have occurred where attempts have been made to remove a foreign body which was not present—so that we should never be satisfied with the patient's word until we can, by good illumination, actually see the foreign body. Frequently this is quite difficult owing to the tortuous condition of the canal.

The following cases are interesting ones on account of the nature of the injuries:

Case I.—*Lacerated Wound of the Auricle.*—Theo. S., Austrian, 39 years old, a stableman, was brought to the Infirmary December 20, 1910, in an ambulance, suffering from a severe laceration of the right auricle. The patient was working in an elevator, and fell, striking his head against a wagon. The lower third of the auricle was almost torn off and the wound extended into the cartilaginous canal and tragus. The patient refused to take an anesthetic. I had to put in fifteen or twenty sutures, which brought the edges of the wound nicely together. The cartilage was not included in the sutures—only the integument. Sterile gauze was placed over the auricle and a bandage applied. On December 24 the sutures were removed and the wound healed by first intention. (Figs. 1 and 2.)

Case II.—*Removal of a Bean in the External Auditory Canal, by Displacing the Auricle Forward.*—P. R., a boy, aged 8, came to the Infirmary on November 15, 1909, with the history of having gotten a bean in the left ear during the morning. He was seen by four doctors before coming to the hospital, who attempted to remove it, but simply pushed it beyond the isthmus against the drumhead. On the following day, when the boy was anesthetized, I found it necessary to displace the auricle forward as it was impossible to remove it otherwise. I made an incision over the mastoid process, close to the auricle and down to the bone, and pushed the posterior portion of the cartilaginous canal forward so that I could remove the foreign body from the bony auditory canal. The wound was sutured and healed by first intention, and the patient left the hospital in a week's time.

Case III.—*Rupture of the Drumhead and Probable Fracture at the Base of Skull.—Mastoid Operation.*—R. R., aged 18, a student at Princeton, on October 18, 1905, fell on the tiles of the bathing-pool, striking the right side of the head about an inch above the upper border of the auricle. He was unconscious for about five minutes. There was immediately a small swelling at the point of injury. There was no dizziness, but bleeding from the right ear. He was put to bed and kept quiet for a week. On October 26 I was called in to see him, as he had a severe earache followed by a profuse serous discharge, and a temperature of 102 deg. F. The watch was heard close to the ear, and the voice was fairly well

heard. There was a perforation in the upper posterior quadrant, and I made a diagnosis of probable fracture through the petrous bone. The secretion from the auditory canal was examined under the microscope, and no pus cells were found. Staphylococci and a few streptococci were found. Tests made with the tuning-fork showed that the auditory nerve had not been affected. There was slight tenderness over the mastoid antrum on October 26, but on November 1 it was very marked, and also extended over the lower half of the mastoid bone. At this time, November 1, the discharge was a little less, but still profuse. From October 26 to November 1 the temperature varied from normal to 100.8 deg. F. I advised a mastoid operation, which I performed on November 2, and after opening the mastoid cells in the usual manner found very extensive softening and pus throughout the entire mastoid bone. The latter was of the pneumatic variety, and contained cells running very deep posteriorly and behind the tip, also in the zygomatic fossa. The contents of the mastoid were entirely removed, and the cavity was irrigated with a saline solution. The wound was packed with sterile gauze and partly sutured above and below. The patient made an excellent recovery.

Fig. 1.—Lacerated wound of the right auricle, before operation.

Fig. 2.—Same as Fig. 1, after operation.

Case IV.—*A Case of Acute Suppurative Inflammation of the Middle Ear and Mastoid Cells, Due to a Blow from a Tennis Racket.*—Esther L., 24 years of age, consulted me November 17, 1908, and said that she had been struck on the right mastoid process with a tennis racket ten weeks ago, and a week later the ear began to discharge. The pain has been severe in the ear and the mastoid region since the accident. At times she has felt chilly, and she has had some fever. There is a distinct fluctuation in the soft tissues over the mastoid process. Under ether anesthesia I opened, on November 18, the subperiosteal abscess and found a sinus in the outer wall of the mastoid process at the tip. The mastoid was filled with pus and granulations, with deep cells extending posteriorly and below. The dura and sinus were not exposed. After removing the contents of the mastoid the wound was irrigated with a saline solution and packed with sterile gauze, and the upper and lower edges of the wound were sutured. The wound healed in eight weeks' time, as well as the drumhead, which was considerably thickened. The hearing was: Right ear, watch, 33 inches; left ear, 49 inches. Whispered words were fairly well heard on the left side, but not quite so well on the right side. There was some thickening and retraction of the left drumhead.

Case V.—*A Case of Rupture of the Drumhead, with Labyrinthine Involvement, Following a Boiler Explosion.*—Peter D., 38 years old, married, was sent to me October 30, 1910, on account of deafness of the left ear. Eleven days ago a boiler exploded where he was working, and five men were killed, who were near the boiler. He happened to be in another part of the room, where he had gone to open a window, and in this way escaped death. The right ear was directed toward the window, while the left one was exposed to the boiler. He was rendered unconscious for about ten minutes and on regaining consciousness escaped through the open window. He had two ribs broken. He was burned about the back, his left ear and auditory canal. He had vertigo immediately after the accident, with extreme deafness, and ringing and buzzing sounds in the left ear, which have gradually diminished. An examination showed that there was some diffuse thickening and retraction of the right drumhead. On the left side there were burns on the auricle and external auditory canal. There was dried blood on the anterior half of the membrana, and some on the inferior wall of the canal, with an undoubted rupture of the drumhead along the handle of the malleus. Left ear.—Loud voice was heard at 12 feet. Watch, 0. Acoumeter, contact. Gallon whistle, 5.5 at a distance of 20 feet. Tests carefully made with tuning forks showed some impairment of the labyrinth, especially for the lower tones. The hearing has improved somewhat since the accident, and the ringing noise is less. On November 14 the hearing for the acoumeter was ½ inch, but on the 21st the hearing was not so good, and the evidences of labyrinthine disease were more marked. Pilocarpine treatment was commenced to-day. On November 30 he seemed better in every way. Hearing improved, noises less, and pain about the ear, which he had complained of for some time, had disappeared. December 10.—Pilocarpine treatment has been continued. He complains again of severe pain about the ear and temple. Noises make him nervous. His wife had to stop using a sewing machine on his account. March 11.—He has

had constant pain in the ear ever since last visit, with some tinnitus at times. His hearing remains improved. He has been employed as a watchman, as he tried to work in the shop, but could not stand the noise. When using the hammer he said he had severe pain in the ear, and the buzz-saw caused a distressing tinnitus. After this visit he passed from observation, and I understand has brought suit for damages against the company.

Case VI.—*A Case of Labyrinthine Disease Following a Fall.*—N. O., a boy, 8 years old, was brought to my office on November 15, 1907, with the history that on November 5 he had fallen off a railing about 12 feet in height, striking the left side of his head against the concrete. An ambulance surgeon dressed the scalp wound, which was two or three inches above the upper border of the auricle. The boy was unconscious about twelve hours, and bled profusely from the left side of the nose for six hours. He vomited blood for nine hours after the accident. The vomiting continued the next day, but without blood. He cannot apparently hear anything, and he can only be made to understand by writing. There has been no dizziness, nor staggering gait. He eats and sleeps well now. He feels a slight sound when a vibrating tuning fork is placed on the mastoid bone. On examination there was found slight redness along the handle of each malleus, and on the upper walls of the external auditory canals. There was no rupture of either membrana tympani, and the seat of the trouble was in each labyrinth.

The subject of injuries of the ear is a most important one, and I have been able only in a brief way to refer to some of the most important points.

I would emphasize particularly the following conclusions:

First, and above all, don't rely on the patient's statement, but be sure, with good illumination, that a foreign body is present, and in most cases a syringe and warm water will be all that is necessary to remove it, unless it has become swollen or impacted. So many injuries are due to the inexperienced attempting to remove foreign bodies with instruments. Then, again, syringing the ear, the use of drops, etc., in traumatic ruptures of the drumhead are always contraindicated, and many a case of rupture of the membrane would have healed if left to nature.

Finally, the medicolegal question is a most important one, and the difficulties are great in deciding as to whether an injury is due to traumatism, unless seen immediately or very soon after the supposed injury.

Many years ago I reported a case with the late Dr. Roosa, in which we were called to court for the defendant, who had slapped a boy's face for maltreating his children. The suit was brought for $10,000 damages. The boy had adenoids and enlarged tonsils, and his hearing was affected on both sides, and was proved to have been due to the presence of adenoids and tonsils and not to the alleged blow. Where the drumhead has been ruptured, the presence of blood in the canal and on the edges of the opening are characteristic, while the mucous membrane of the middle ear will appear normal, if it can be seen through the perforation. On the other hand, if the injury has been followed later by a purulent discharge it is impossible to state that the supposed injury is the cause of the disease. In such cases the edges of the perforation are swollen and red, as well as the mucous membrane of the middle ear.

A diagnosis of involvement of the labyrinth can be made by means of the tuning-fork. We find diminution or loss of bone conduction as shown by the tuning-fork, together with symptoms of sudden deafness, tinnitus, dizziness, a staggering gait, a feeling of fulness in the head, and nystagmus. The drum membrane is usually intact in such instances, but it remains for the patient to prove that an injury, fall or explosion was the cause of such labyrinthine symptoms, and that his hearing was good before the supposed accident, as involvement of the inner ear may be due to other causes.

PEDIATRIC MEMORANDA.

PNEUMOHYPODERMA (EMPHYSEMA CUTIS). SCLEREDEMA NEONATORUM.

By HERMAN B. SHEFFIELD, M.D.,

NEW YORK

Pneumohypoderma.—With antitoxin treatment of diphtheria, and intubation, instead of tracheotomy, in laryngeal stenosis, nowadays there is rarely the opportunity to observe as severe a case of subcutaneous emphysema as the one here reported. (See Fig. 1). In this instance rupture of pulmonary alevoli and escape of air into the subcutaneous tissues occurred in consequence of violent coughing during an attack of bronchopneumonia complicating measles. The little girl was three and a half years old and up to the present illness in good health. Her parents were Italians of the old school and firm believers in having the windows tightly shut. To be doubly protected against a draught, the windows and doors were fortified by heavy draperies. As I approached the patient I

Fig. 1.—Emphysema Cutis.

was startled by a ghastly sight. Deeply imbedded in a mass of soft pillows, there lay a waxy, rotund face with bluish black lips, which were rapidly but rhythmically flapping back and forth with inspiration and expiration. The child's features were entirely effaced, and its Kalmuck-shaped, congested eyes were deeply sunken between the highly puffed lids. On lifting the feather bed and blankets I noted the marked contrast between the emaciated lower extremities and the inflated trunk and upper extremities. On palpation a distinct purring (crepitation) was transmitted to the fingers, and on gentle compression of the almost bursting skin it imparted a sensation very much akin to that experienced when touching a tense toy balloon. The patient coughed violently and was in great distress gasping for air. The respirations ranged between eighty and ninety per minute; the pulse was weak and rapid, about 150 per minute) and the heart impulse was effaced. The temperature was 102.5° F.

There was no difficulty in arriving at a correct diagnosis. The total freedom of the lower extremities and the absence of pitting readily ex-

Fig. 2.—Scleredema Neonatorum.

cluded renal or cardiac dropsy; and the acute onset and the distinct purring on palpation eliminated the possibility of edema following compression of large intrathoracic blood vessels by a growth or by large tuberculous bronchial glands.

The prognosis was given with a great deal of reserve, but thanks to the assiduous and skillful care on the part of the attending physician, Dr. F. Fortunato (who kindly consulted me on the case), the child recovered completely within four weeks. Medicinally, the treatment consisted in the administration of small doses of codeine, to arrest the cough, and infusion of digitalis to sustain the heart.

Edema Neonatorum.—This case is of particular interest because it failed to reveal the usual etiological factors of the disease. That is, the child was born at full term; weighed eight pounds; was not asphyxiated; was apparently free from congenital syphilis, and showed no local infection. The baby seemed well up to the sixth day, when a slight edema was noted. Six days later I saw her in the hospital with marked edema, especially of the lower and upper extremities, including the soles of the feet and palms of the hands, face and lower part of trunk. The skin was bluish white and shiny. The edematous portions were doughy to the touch and left a deep impression when pressed upon with the finger (See Fig. 2). Careful and repeated examinations of the urine failed to disclose any kidney lesion, except for a trace of albumin which is commonly met in the newly born. The quantity of urine was greatly diminished, but this was probably in part due to refusal of the child to take nourishment. The temperature, per rectum, was 97° F. The heart's action was weak, and somewhat irregular. No heart lesion could be elicited.

In its differentiation from sclerema adiposum, for which scleredema is apt to be mistaken, I was guided by the following differential points:

Scleredema.	*Sclerema Adiposum.*
Color of skin, shiny, mottled.	Dirty yellow.
Parts exempt, chest.	Genitals; palm of hands; soles of feet.
Facial features, quite normal.	Marbleized.
Pitting on pressure, marked.	Absent.

The edema disappeared entirely in about six weeks on the administration of two grains of postassium acetate and ten drops of infusion digitalis every four hours, and regulation of diet.

127 West Eighty-seventh Street.

SOME SUGGESTIONS REGARDING THE MEANS OF DETECTING ADVERSE SELECTION.*

By ARTHUR B. WOOD, F.I.A., F.A.S.,

MONTREAL.

ACTUARY SUN LIFE ASSURANCE COMPANY OF CANADA.

Of the various factors on which the success of a life assurance company depends, none can be regarded as of more vital consequence than the care exercised in the selection of risks. That the mortality experienced should fall within that predicted by the table on which the premiums are based is of fundamental importance.

The usual standard mortality tables prescribed for valuation purposes and generally employed as the basis of premium calculations are derived from the past experience of assured lives accepted at ordinary rates, and can therefore be relied upon as safe guides for the future, provided that reasonable care be exercised in the selection of lives. As a matter of fact, owing to the gradual improvement which has taken place in recent years in the methods of medical selection and our constantly increasing knowledge of the mortality prevailing in various classes of lives, every well managed company in these days succeeds in obtaining an aggregate mortality considerably lower than the expected according to such standards, or in other words a substantial profit from mortality is realized and is looked for as a mark of successful management. Consequently, to obtain a proper conception of a company's death rate, comparison should be made, not with the expected deaths by such a table as the American or the H^{m}, but by a standard "Select" mortality table, that is, one which shows the rates

*Read at the annual meeting of the Association of Life Insurance Medical Directors, October 4 and 5, 1911.

of mortality according to years of assurance, or, in other words, which makes allowance for the benefits expected to be derived from medical selection. In the present state of our knowledge the margin provided in the premium rates should be sufficient to safeguard the interests of any company. As a rule, the greater degree of leniency exercised by some companies than by others in the acceptance of lives merely has the effect of somewhat reducing the amount of profit derived from mortality.

Every medical referee naturally desires to obtain a low mortality rate for his company, and it is, of course, important that a normal profit from this source be maintained, especially in these days when competition is being directed so strongly along the lines of paying large dividends. At the same time he should not permit his anxiety to realize large profits from mortality to influence him to be unnecessarily severe in the rejection of applicants. He should bear in mind that an extremely low mortality is but one mark of successful management and that undue strictness may work against the company through the dissatisfaction caused in the agency staff as well as in other ways. Then again, the duty of a life assurance company towards the public should not be overlooked. To best justify its existence a life assurance company should endeavor to extend the advantages of protection to all who can reasonably be granted assurance, even if a somewhat smaller profit for mortality be realized than would obtain if none but unquestionably gilt-edged lives were accepted. The medical referee should therefore aim at striking a happy medium and should endeavor to reject as few lives as possible which are really deserving of assurance. The so-called border-line cases should be treated with as great a degree of leniency as is consistent with safety and the maintaining of a reasonable amount of profit from mortality. The commendable practice of devising plans for assuring lives that are clearly under the average should also be encouraged, for no class in a community is in greater need of the benefits of protection. The realization of this fact is to a large extent responsible for such undertakings as the Specialized Mortality Investigation of 1903 and the Medico Actuarial Investigation now in course of preparation. The latter is without exception the most extensive work ever undertaken along these lines, and the information which it will supply should result in a wide extension of the benefits of life assurance. Many companies will probably see fit to make marked changes in their methods of selection, and the practice of assuring under-average lives should also become more common.

But while in justice to the company, the agents, and the public, the medical referee should endeavor not to be unnecessarily severe, it is equally important for him to bear constantly in mind that if a risk be of a speculative nature it should be declined, no matter how good the physical examination may appear to be. Experience teaches us that in spite of the most careful examination many lives find their way to the books of the company which, in the light of subsequent events, should never have been accepted on any terms. These are the lives involving the so-called moral hazard. If proper precautions be taken to eliminate all such undesirable cases the company's mortality may be substantially improved without causing injustice to anyone. Many companies could probably well afford to be more lenient with deserving cases if more pains were taken to guard against risks of a purely speculative character. As these lives manage to escape notice, in spite of the medical examination, other means of detecting them must be adopted, and the object of the present paper is to direct attention to some of the classes of lives in which the element of adverse selection is especially noticeable, and to certain characteristic features which serve as danger signals to place us on our guard. I am inclined to think that some medical referees do not give to this phase of selection the prominence it deserves, and I wish to emphasize the importance of paying as close attention to these other features as is given to the physical examination and family history.

VALUE OF MEDICAL SELECTION.

All insurance officials are fully alive to the value of the work performed by our medical departments. It is true that we sometimes hear it said that selection by medical men might be dispensed with, and occasionally we meet with an agent who claims that he is quite as capable of judging of the eligibility of an applicant for insurance as the medical examiner. It is possible that under certain conditions and by adopting proper safeguards to eliminate the element of speculation, a fairly satisfactory mortality might be obtained without medical examination. For example, in the early days the British companies simply demanded a certificate of health and required the applicant to appear before the Board of Directors, when he was accepted or rejected according as they took a favorable view of his case, or otherwise. This practice was continued by the Amicable as late as the year 1855. As a matter of interest and to illustrate the effect of these early methods of selection, I have compared the experience of the Amicable prior to 1841 with the Institute of Actuaries H^m table. The actual deaths were 798 and the expected 815, giving a ratio of actual to expected of 98 per cent. The mortality, although much heavier than would be experienced under modern methods, was nevertheless satisfactory as compared with the premiums charged in those days. But we must remember that in those days the amount of business transacted was small and the field of operations limited in extent. Such methods would hardly be practicable under present day conditions. Still, the results achieved by the companies in the early days of life assurance impress upon us the effectiveness of the personal inspection on the part of the directors. A certain proportion of the lives would, undoubtedly, have been rejected under a strict medical examination, but on the other hand the personal inspection probably was the means of eliminating most cases of a purely speculative nature.

To illustrate the benefits derived from medical selection we need merely compare the rates of mortality in a body of recently selected lives with the corresponding rates in the general population. For example, according to the British Offices O (m) table the rate of mortality at age 35 at entrance during the first policy year is but 3.61 per thousand as compared with 11.27 by the English Life Table No. 3 (males), a ratio of but 32 per cent. and even in the tenth year after acceptance it has risen to but 11.89 per thousand, while by the English No. 3 table the rate is 14.86, the ratio being 80 per cent.

If further evidence were needed, an even more effective argument might be based upon the after history of the rejected lives. Owing to the difficulty of keeping such lives under observation little information regarding them is obtainable, but an inter-

esting paper appears in the *Transactions of the Actuarial Society of America*, vol. iii., p. 225, where Mr. Walter S. Nichols has compared the average death rate amongst 13,042 lives declined by the Prudential Insurance Company with the general death rate of the company. The after history of the rejected lives was followed by means of prior existing policies on those lives. During the five years immediately following rejection 1440 deaths occurred among the declined lives, while according to the average general death rate of the company during the same period there would not have been more than 443 deaths. Among the declined lives the death rate was therefore 325 per cent. of the general death rate of the company. Even in the six months immediately following rejection, the death rate was about 52.1 per thousand as compared with the company's general death rate of only 17.7 per thousand. The author says, "The explanation of such an excessive mortality immediately following upon the rejection must probably be sought in the fraudulent efforts to select against the company by applicants who knew that their lives were uninsurable." The high death rate among the rejected lives is a forceful illustration of the value of the medical examination.

GOOD FAITH ESSENTIAL.

The contract of Life Assurance is based on the assumption that the applicant shall observe the utmost degree of good faith and shall state all matters within his knowledge which may have a bearing upon the risk. This responsibility, however, is very lightly regarded by many applicants, as we all know from experience; many persons apparently consider that their duty ends with presenting their own case in the most favorable light, leaving the company to discover the unfavorable features, if any, as best they can. The desire to profit at someone else's expense is so deeply ingrained in human nature that a life assurance company must be constantly on its guard against adverse selection.

POWER OF SELF-SELECTION.

The common method of illustrating the power of self-selection and its relative importance to medical selection is to compare the mortality among annuitants with the corresponding mortality in a body of assured lives, and again to contrast both with the death rate according to a table derived from general population statistics. As an example, I give below the rates of mortality for age 35 at entry, according to years of assurance, by the British Offices Male Annuitants Table and the British Offices O (m) Table for assured lives. The corresponding rates by the English Life Table No. 3 are also given as representing the mortality in the general population.

RATE OF MORTALITY PER 1,000.

Policy Year	Attained Age	ANNUITANTS		ASSURED LIVES		General Population
		B. O (am).	Per cent. of Eng. No. 3	O.(m)	Per cent. of Eng. No. 3	Eng. No. 3
1	35	3.81	34	3.61	32	11.27
2	36	5.08	44	5.64	49	11.56
3	37	6.59	55	6.55	55	11.87
4	38	8.12	66	7.22	59	12.21
5	39	9.30	73	7.85	62	12.57
10	44	11.38	76	11.89	80	14.86
15	49	14.65	81	14.65	81	18.07
20	54	19.38	83	19.53	84	23.36

Among both annuitants and assured lives the mortality is permanently much lower than in the general population and is exceptionally low in the early years of assurance. Contrasting the mortality among annuitants with that of assured lives we see that the power of self-selection exercised by annuitants in their own favor is fully as strong and may be even stronger than that of medical selection.

As the self-selection by annuitants is revealed by the light mortality during the early policy years, so also the adverse selection exercised against the company by applicants for insurance manifests itself in the experience of many classes of risks by an excessive death rate, especially during the early policy years. When this feature is observed in any body of lives accepted as apparently first-class risks, it is evident that adverse selection has been more powerful than that exercised by the office. This point will be illustrated as I proceed.

INSURABLE INTEREST.

I would, however, first direct your attention to the question of insurable interest, for this is of fundamental importance in the selection of lives. The contract of life assurance is designed to protect the beneficiary against loss occasioned by the death of the assured, but it does not fall within the scope of the contract that persons without any interest in the event insured against should be permitted to profit thereby. All risks in the nature of gambling transactions are invalid as being opposed to the spirit and purpose of the contract as well as against public policy. It is by no means an easy matter to define what will in all cases constitute an insurable interest, so as to take the contract out of the class of wagering policies; but to quote from May *On Insurance*, "to have an insurable interest in the life of another, one must be a creditor or surety, or be so related by ties of blood or marriage as to have a reasonable anticipation of advantage from his life. Whenever there is such a relationship that the insurer has a legal claim on the insured for service or support, or when from the personal relations between them the former has a reasonable right to expect some pecuniary advantage *from the continuance of the life of another*, or to fear loss from his death, an insurable interest exists." For example, every person has an insurable interest in his own life; a married woman in the life of her husband; a child in the life of a parent of whom he or she is dependent for support; a creditor in the life of his debtor; a partner in the life of a co-partner; and, generally speaking, any one person has an insurable interest in the life of another whose death would result in financial loss to him. On the other hand, under English law at least, a husband is not presumed to have an insurable interest in his wife's life, but if he is dependent upon his wife for support, or is in receipt of an income which would cease at her death, an insurable interest clearly exists. Lack of insurable interest should of itself be regarded as a sufficient reason for rejecting a risk.

To determine the question of insurable interest, truthful answers must be obtained to questions such as these:

Who will actually benefit by the policy applied for?

Will the beneficiary sustain any financial loss by the death of the assured?

From what source are the premiums to be paid?

If these inquiries reveal the fact that the assured's death will not result in financial loss to the beneficiary, but on the contrary the assurance will be an

actual source of profit, the case should be declined as speculative. I wish here to lay particular stress upon the importance of ascertaining who really intends to pay the premiums. If they are to be paid by the beneficiary the risk is seldom one which the company should assume.

The apparent existence of an insurable interest does not, however, always justify the acceptance of a risk. Although every person has a right to effect an insurance on his own life, if the intention is to assign the policy to a third party who has no insurable interest and who really intends to pay the premiums, the risk should be regarded as speculative. It is therefore important to inquire whether any assignment is being contemplated.

CREDITORS' POLICIES.

A creditor undoubtedly has a legal right to insure the life of his debtor, but such policies as a class have been found to be unsatisfactory, particularly if the creditor is paying the premiums. It is not at all uncommon for creditors to effect assurance upon the lives of their debtors, in cases where the recovery of the debt is considered hopeless. The existence of the debt is probably sufficient to constitute a legal interest in the life, although it is quite obvious that in such a case the creditor's real interest must be in the death of his debtor. A person who under such circumstances is willing to risk the life assurance premiums in addition to an existing debt has probably some good reason for believing that his debtor will not live his alloted span. The point to be emphasized is that a strict legal interest may co-exist with a thoroughly speculative assurance.

The objection to creditors' policies does not apply to the same extent where the assured is personally paying the premiums, but it is often difficult, and frequently impossible to obtain accurate knowledge of the real nature of the transaction. All such cases should therefore be regarded with suspicion, and subjected to a careful investigation. It should also be remembered that this class of lives consists chiefly of persons in financial difficulties, subject to severe mental and nervous strain, which is not conducive to longevity.

FINANCIAL CONDITION

The relation of the amount of assurance applied for to the applicant's financial condition furnishes a valuable clue to the presence of adverse selection. If the amount appears unreasonably large, careful inquiries should be made to ascertain whether the applicant's income justifies his assuring for such a large sum. If a satisfactory explanation be not forthcoming, the case must be regarded with suspicion. Adverse selection under policies for large amounts is well illustrated by the experience of Class I of the Specialized on policies of $20,000 or over on one application. The following synopsis of the results is exceedingly instructive:

POLICIES OF $20,000 OR OVER.

PERCENTAGE, ACTUAL DEATHS OF EXPECTED BY ACTUARIAL SOCIETY STANDARD—INSURANCE YEARS

Age at Entry	1–5	6–30	1–30
15–28	118.6	81.0	100.7
29–42	105.1	103.4	104.2
43–56	107.3	105.8	106.2
57–70	130.7	120.6	125.4
All ages	110.5	105.8	107.8

The mortality as a whole is unsatisfactory, the total actual deaths exceeding the expected by 7.8 per cent. If, however, we examine the experience according to separate groups of entrants, and according to duration, we are warned where to be particularly on our guard in dealing with policies for large amounts. In the age group 15 to 28 at entry, the mortality for all durations combined was almost exactly normal, 100.6 per cent, but the actual deaths during the first five years of assurance exceeded the expected by 18.6 per cent; after five years the mortality was favorable, being only 81 per cent. of the expected. Although the number of lives contained in this group is not very large, I think we are nevertheless justified in concluding that the heavy mortality during the first five years of assurance was due to the speculative risks which the companies did not succeed in eliminating. In the age groups 29 to 42 and 43 to 56, the principal ages at which assurances are taken out, there is no marked difference between the ratio of the actual to the expected deaths during the first five years and thereafter, but the mortality was somewhat above the normal throughout. When, however, we come to the old lives aged 57 to 70 at entrance, we find a ratio of actual to expected of 130.7 during the first five years, and 120.6 per cent. thereafter. The mortality in this group of entrants was excessive throughout the whole duration of the policies, but was considerably heavier during the first five years of assurance than subsequently. It is evident that many lives of a speculative character succeeded in obtaining assurance in spite of the most careful medical examination. These results impress upon us the necessity for exercising unusual care with every application for a large amount, but we are particularly warned to be on our guard if the applicant be either very young or advanced in years. Not merely is it necessary to examine with more than usual scrutiny the physical qualities of such risks, but it is of even greater importance to ascertain in each case whether there is a valid reason for the insurance. Does the object for which the assurance is being taken out commend itself to our judgment? And is the applicant personally able to pay the premiums without assistance from any other source?

In considering the relation between the amount applied for and the applicant's financial condition, account must also be taken of any existing assurance. A considerable amount of assurance recently taken out should arouse our suspicions, but a large amount of existing assurance taken out at intervals, extending over a number of years, is a favorable indication.

Applications for further assurance shortly after the issue of a policy for a moderate amount should also be carefully investigated. Instances are known where the first application has been submitted merely as a test case, and being for a small amount has been accepted without hesitation, whereas if the larger sum had been applied for originally, the company's suspicions would have been aroused. It is also important to inquire whether any application is being made at the same time to any other company.

AGE AT ENTRY.

The important bearing of the age at entry on adverse selection is observed not only in connection with policies for large amounts, but also in the general experience of most companies. Adverse selection appears to be constantly at work both at the

young and at the advanced ages. Most published experiences exhibit a heavy death rate among persons entering at the young ages, 15 to 25. I do not propose to quote any more figures than are necessary for the purpose of illustration, but will merely take as an example the Institute of Actuaries' experience H^m on lives entering at ages 15 to 25. The actual deaths in this group were 1,631 as compared with 1,410 expected by the H^m table itself, the ratio of actual to expected deaths thus being 116 per cent. The mortality was excessive both during the first five years of assurance and thereafter. The same feature is observed to an even more marked degree in the Thirty American Offices' experience, as well as in that of many individual companies. It is evident that we must be unusually careful at the young ages. Defects in the personal or family records of these young applicants should be regarded as of much more serious consequence than in the case of persons more advanced in age, and special attention should be paid to the object for which the assurance is being taken.

On lives entering at the advanced ages, some companies have had a very satisfactory experience, while, on the other hand, many instances can be cited in which these old entrants have proved very unprofitable. The experience of the Equitable Life Assurance Society on lives entering at ages over 60 is given by Mr. Hann in the *Transactions of the Actuarial Society of America*, vol. vi., p. 54, the actual deaths being compared with the expected by the American experience table, and in the discussion of the same paper appear the corresponding figures for the Connecticut Mutual Life and the Mutual Benefit Life combined. The percentages of actual to expected deaths are as follows:

AGES OVER 60 AT ENTRY.
PERCENTAGE ACTUAL OF EXPECTED DEATHS BY AMERICAN TABLE

Years of Assurance.	Equitable	Conn. Mutual and Mutual Benefit
1–5	97.25	67.94
6–10	98.75	76.93
11 and over.	93.44	94.05
Total	96.87	78.98

The difference in these experiences is very marked. During the first five years of assurance the ratio of actual to expected deaths was 97.25 per cent. in the first-mentioned company, while in the other two it was only 67.94 per cent., or allowing for the benefits of selection, merely normal. The ratio is also much heavier during the years of assurance 6 to 10 in the first company than in the other two. Mr. Hann remarks: "Medical selection is evidently at its worst in dealing with proponents for assurance at advanced ages. The most careful attention should be paid to their family history, habits, financial standing, and general environments. Where there is any doubt on any material point, our motto should be 'Decline.'"

I would add that the importance of ascertaining the real motives prompting the assurance cannot be too strongly emphasized. Careful inquiry should be made to determine whether there is a legitimate reason for the assurance; and also the source from which the premiums are to be paid. If, for example, the beneficiary be a grown-up son or daughter, and the premiums are to be paid by the beneficiary, the risk should be treated as speculative, and should be declined for this reason if for no other.

Some companies take the position that all risks over 60 years of age should be rejected. This is undoubtedly a safe course, but would appear to be entirely too drastic. Many men at these advanced ages have persons dependent upon them who really need the protection of a life insurance policy, and if proper safeguards are adopted to insure the acceptance only of those cases where a real need for the assurance is shown to exist, all others being declined, I am satisfied that a favorable mortality can be obtained in this class.

PLAN OF ASSURANCE.

Investigations of the mortality under different plans of assurance have proven that we may always look for adverse selection under cheap forms of policy. The mortality appears to vary inversely with the premium. The most striking illustration of this point is found in the British Offices' experience 1863-1893. In the *Transactions of the Actuarial Society of America*, vol. vii., p. 117, Mr. Arthur Hunter has compared that experience with an Assumed American Standard, which can be regarded as conforming approximately to the experience of the average company on this continent. The following ratios of actual to expected deaths by the Assumed Standard are exceedingly instructive.

BRITISH OFFICES EXPERIENCE, BY PLAN OF ASSURANCE.
RATIO OF ACTUAL TO EXPECTED DEATHS.—INSURANCE YEARS.

Class of Insurance.	1–5	All Years Combined.
Term Assurances	131%	123%
Whole Life, without Profits	139%	127%
Whole Life, with Profits	98%	110%
Limited Payment Life Policies	71%	76%
Endowment Assurances	70%	81%

Adverse selection is clearly indicated by the heavy mortality under the Term and Whole Life, Non-participating plans, the ratio of actual to expected in each of these classes being considerably higher during the first five years of assurance than for all years combined. On the other hand, under the higher-priced policies, such as the Limited Payment Life and Endowment Assurance plans, an exceedingly low rate of mortality was experienced both during the first five years and subsequently. It is but natural that persons who have little confidence in their prospects of longevity should desire to get the maximum amount of protection for the least money. They therefore select the cheaper forms of policy. Consequently, such applications should be criticised with unusual care, and we should look with suspicion upon even minor defects which, in the case of the investment form of policies, might be regarded as of practically no importance.

FEMALE LIVES.

The practice of insuring female lives has increased rapidly in recent years with the entering of women into various business pursuits. There is undoubtedly a legitimate field for assurance among women, but at the same time there is probably no class of lives in which the risk of adverse selection is more prominent. The mortality among female lives furnishes a most interesting field for study. According to general population statistics, the mortality among females is on the whole even lighter than among males, and in some tables is slightly lower even between the ages of 20 and 45. If, however, the statistics be divided into single and married persons, respectively, it will be found that among single females the rate of mortality is some-

what lower than among single males, while among married females the death rate for ages up to about 45 is considerably higher than among married males and is lower during the latter half of life. Turning to life companies statistics, we find that among female annuitants the mortality is very light, making it necessary to charge females higher rates for annuities at all ages than males. On the other hand, in most general experiences of female assured lives, the death rate exceeds that of male assured lives. The explanation is apparent. The great majority of those who purchase annuities are single women and all are self-selected lives who have every confidence in their prospects of longevity. The higher death rate under female assured lives is probably due to the fact that the proportion of married women accepted is larger than exists in the general population, and that many of the female risks have been of a speculative character. The selection exercised against the companies by female lives is powerfully shown by the experience of the British Offices. In Mr. Hunter's paper, previously referred to, it is shown that the mortality among women who were accepted on the Whole Life with profits plan was exceedingly heavy, especially during the first five years of assurance. The ratio of actual to expected deaths by the Assumed American Standard was 132 per cent. during the first five years, and only 114 per cent. for all years combined. The importance of the plan of assurance is seen by comparing with the above figures the mortality under female lives accepted by the British Offices on the endowment plan. The experience is not given by years of assurance, but only in the aggregate. However, I find that while the actual deaths were 303, the expected by the full American experience were 447, the ratio of actual to expected being only 67.7 per cent. The mortality was evidently very favorable at all durations among women who insured on the endowment plan.

A great diversity of practice exists among companies in dealing with female lives. Some accept them freely on the same terms as men. Others accept only certain classes and under special regulations, while others do not accept them at all. Whether a company's experience will be favorable or unfavorable will depend entirely on the nature of the precautions taken to weed out the undesirable lives. While the normal extra risk for married women during the child-bearing period can be covered by a moderate premium, it is practically impossible to fix an extra which will be a sufficient protection to cover speculative risks. The all-important point to determine is the real motive prompting the insurance. We must satisfy ourselves that a legitimate reason for it exists. The importance of giving careful consideration to the question of the person who is to benefit by the assurance and the source from which the premiums are to be paid, is well illustrated by the experience of the New York Life as given by Mr. Hunter in his paper on "The Mortality among Women" (*T. A. S. A.*, vol. xii., p. 446), from which the following extract is taken:

Class.	Ratio of Actual to Expected Deaths by Compound Progressive Table.
Married women with children, premiums paid out of own income, children beneficiaries	90%
Married women with children, husband paying premiums, husband beneficiary	113%
Married women, no children, husband paying premiums, husband beneficiary	126%

In the first class where there is a legitimate reason for the insurance the mortality was very favorable indeed, but in the other two classes where the husband was the beneficiary and paid the premiums it was decidedly unfavorable, especially where there were no children.

Where the applicant is an unmarried woman earning her own livelihood, a valid reason for the insurance exists, and such business can safely be accepted on the same terms as apply to male lives. If the applicant be a married woman, and an insurable interest is shown, the risk can be regarded as acceptable, at least with a small extra premium to cover the risk during the child-bearing period, but policies on the lives of married women, payable to their husbands, should be rejected, unless it is proven to the satisfaction of the company that the husband has an insurable interest in her life, and would actually suffer financial loss by her death.

Other undesirable classes of female lives are young women dependent on others for support, and applying for cheap forms of policy, and also elderly women assuring in favor of grown-up sons or daughters. If a company exercises wise discretion in selecting female lives and adopts regulations restricting the business to those classes in connection with which a valid reason for the insurance is proven, or to investment forms of policies, a very satisfactory experience should result.

OCCUPATION.

In certain occupations the risk due to adverse selection is especially noticeable. Persons whose occupation brings them in contact with vice, such as saloonkeepers and gamblers, are very undesirable risks, for however good such individuals may be physically they are constantly subject to influence unfavorable to health and habits.

All investigations into the mortality among persons engaged in the liquor trade show a heavy death rate, and this is usually provided for by charging a suitable extra premium. The specialized mortality investigation showed an excessive mortality even among the most favorable classes of persons engaged in such occupations. For instance, among wine or liquor sellers who warranted that they were abstainers, the ratio of actual to expected deaths was 106.6 per cent. during the first five years and 127.6 per cent. thereafter; and this class, it must be remembered, comprised only cases carefully selected by the companies, and accepted without extra premium. Although abstainers when first assured, many apparently developed bad habits subsequently.

The necessity for charging an extra premium for persons engaged in the liquor trade is, of course, universally recognized, but the point which I desire to emphasize is that selection against the company is more to be feared in this class of lives than among persons following any of the ordinary occupations. No company can afford to accept risks of a speculative character, even with an extra premium. In most investigations of the mortality in the liquor trade the results are given in the aggregate only and therefore throw little light on the question of adverse selection, but in a paper presented to the Fifth International Congress of Actuaries in 1906, Mr. J. Macdonald has given the experience of the Prudential Insurance Co. of London, England, among persons engaged in the liquor trade, under the Whole Life and Endowment Assurances respectively and according to years of assurance. The actual deaths are compared with the expected by

the British Offices' Om Table and the ratios as follows:

Ratio of Actual to Expected Deaths by Om Table.

Plan.	First 5 Years.	After 5 Years
Whole Life	249%	188%
Endowment	163%	185%

Among those who insured on the Whole Life plan, the ratio of actual to expected deaths was 249 per cent. during the first five years, but only 188 per cent. thereafter. Under endowment assurances, on the other hand, the ratio was but 162 per cent. during the first five-year period and 185 per cent. thereafter. We naturally expect a heavy mortality among persons following these occupations, but the lesson to be drawn from statistics such as the above is that speculative risks are to be looked for among those who apply for cheap forms of policies. We have little to fear if the Endowment plan be chosen, but such cases can, as a rule, be safely accepted with the ordinary extra to cover the occupation risk.

There is also a special hazard attached to lack of intelligence. A man who cannot sign his name is hardly in a position to comprehend the full import of the question asked in the application and medical reports, and cannot have a proper conception of the responsibility imposed upon him to act in perfectly good faith. As an illustration I would refer to the experience of the Specialized on Common Laborers. These were found to be very unprofitable risks, as the following synopsis shows:

COMMON LABORERS.

Ratio of Actual to Expected Deaths by Actuarial Society Standard.—Insurance Years.

Ages at Entry.	1–5	6–30	1–30
15–28	113.2	82.0	98.3
29–42	132.1	109.1	119.7
43–56	172.9	129.7	145.6
57–70	208.9	129.2	167.7
Total	139.6	110.6	123.9

Except among the young entrants the mortality was exceedingly heavy throughout. In each class of entrants it was much heavier during the first five years of assurance than afterwards, and the ratio of actual to expected deaths becomes greater the older the age at entry. That adverse selection is very powerful in this class of lives is clearly indicated by the heavy mortality, especially during the first five years of assurance.

Other instances might be given, but the preceding examples are sufficient to illustrate the importance of the factor of occupation.

HABITS.

The necessity of making a thorough investigation into the habits of an applicant where the case is of a suspicious nature is so well understood by every medical referee that I need merely refer to it here.

BUSINESS FROM OUTSIDE SOURCES.

Another class of undesirable business consists of cases not actually canvassed by an agent of the company, but which have come to him through some outside source. If an applicant voluntarily applies to have his life assured, his case is one which needs watching. Careful investigation will generally reveal something of a suspicious nature. Business which is offered by agents of other companies is also doubtful, for usually these are cases which the agent feels that for some reason or another his own company will not accept.

The answer to the question in the agent's report, "How long have you known the applicant?" often serves as a warning to hold the case in abeyance until a thorough investigation has been made.

Applications from persons residing in a locality where the company is not established and actively soliciting business are also undesirable as a class. Some such cases are the result of personal friendship between the applicant and the agent and may therefore be thoroughly satisfactory, but in the absence of satisfactory explanations it is better to refuse all business of this class, rather than run the risk of accepting some speculative cases. We can never be sure that we are acting on thoroughly reliable information.

METHOD OF HANDLING DOUBTFUL CASES.

It is exceedingly difficult in many instances to absolutely satisfy ourselves that the moral hazard is such as to justify us in declining the application outright, and it is especially hard to convince the agent that a case apparently a good average as far as the medical examination, family and personal history are concerned shall not be granted assurance. Still we should not permit ourselves to be unduly influenced against our better judgment. A satisfactory method of endeavoring to eliminate or at least to minimize the risk of adverse selection in such cases is to offer the applicant a short-term endowment policy, say of twenty years. If he can be persuaded to pay the higher premium on the strength of personally deriving benefit from the policy in the event of his surviving the endowment period, his willingness to do so can reasonably be accepted as evidence of good faith on his part. If the death benefit is what particularly appeals to him, he will probably refuse the policy in the hope that he will yet succeed in obtaining the plan he desires from some other company.

As against this practice it might be argued that in Class 3 of the Specialized Investigation, which comprises cases in which a different form of policy was issued from that applied for, the mortality was unsatisfactory. The experience shows a ratio of 119.6 per cent. of the expected during the first five years of assurance, and 107.6 per cent. thereafter. Such a contention would not be justified, however, without further knowledge of the reasons for the changes of plan. As a matter of fact, it has been quite a common practice among American companies to change the plan and grant endowment assurances to certain classes of somewhat impaired lives, and Class 3 probably consists largely of such cases. If the types of impairment treated in this way are those under which a heavy mortality is anticipatel at the outset, decreasing thereafter, as for instance in the case of an applicant with a consumptive family history, combined with light weight or other unfavorable features, the experience of Class 3 is merely what we would naturally expect. Cases changed to the Endowment plan solely because of a suspicion regarding the moral hazard would probably show quite a different mortality.

There are other unfavorable features to which attention might be called, but I have merely endeavored to bring to your notice some of the most important. In estimating the value of a risk there is probably no factor more difficult to determine than that of moral hazard. There is probably none

where actual experience counts for so much or where the exercise of sound judgment is more needed. The suggestions offered will, I trust, serve to emphasize the importance of adverse selection and may prove of some value, especially to those who are connected with some of the smaller companies. During recent years a vast number of new companies have sprung into existence and such institutions are particularly liable to be imposed upon. They have not the benefit of long-time experience on the part of their medical referees, nor have they the same opportunities of obtaining information regarding doubtful risks as their older competitors. Then again, in the struggle for business, a tendency toward undue leniency in selection is natural. Some young companies also labor under the delusion that as all their business is comparatively new they can afford to be more liberal and still maintain a low death-rate, but, as a matter of fact, losses which would have little effect on the general mortality of an old company with a large volume of existing business might even prove disastrous in their case.

The importance of adopting every precaution to guard against risks of a purely fraudulent nature should be realized by all companies in these days when the incontestible clause has been made so liberal. It is generally understood that fraud will vitiate a contract at any time, but there is a danger of the courts ruling otherwise after the incontestible period has expired, and furthermore most companies would hesitate to contest a claim under such circumstances from the fear of the bad effect it might have upon their business. The wise course is to endeavor to avoid all disputes in the settlement of claims by eliminating the undesirable lives at the outset, even if an occasional good risk may be lost through the adoption of somewhat stringent rules.

A CASE OF RECOVERY FROM PROLONGED BLINDNESS. THE RESULT OF HEMORRHAGE INTO THE VITREOUS.

By DAVID WEBSTER, M.D.,
NEW YORK.

Dr. F. M. H., age 39, married, nose and throat specialist, of Montana, came under my care at the Manhattan Eye, Ear, Nose, and Throat Hospital the first week of March, 1904. He had lost the sight of his right eye, at the age of seventeen, by a sword thrust while fencing. The eye was of normal size. There were total atrophy of the optic nerve and divergent strabismus. On February 22, 1904, he was reclining on a sofa and when he arose he noticed black spots floating before his left eye. He could see the ground the next day, Tuesday, and by noon the Sunday following he had lost all objective vision. He at once started for New York, and arrived at the hospital as aforesaid. Upon examination we found that on attempting to see the fundus we simply looked in darkness. The field of perception was good, the tension was normal, and the pupil responded promptly to light and to accommodative effort. The presumption was that an extensive hemorrhage had occurred and that the vitreous chamber was filled with blood, though no red color could be seen through the pupil by oblique illumination. He experienced photopsia and chromopsia, but no pain. He was apparently cheerful and confident that he would recover his vision, basing his hopes on his quick perception of light and his perfect field of perception. He was taken into the hospital, put to bed, and given pilocarpine sweats for several weeks. Mercury and iodide of potassium were administered *ad nauseam;* also radium was applied several times.

He came to my office September 24, 1904, when I made the following note: The photopsia has grown less; the chromopsia is variable. A dark wave, red and black, comes over from the nasal side and encircles the whole eye. The black spots seem just the same only that they appear farther away. Something seems to have got in between him and them. With the ophthalmoscope a moving, floating mass can be seen. A faint red reflex appears at the nasal periphery of the fundus. No limited or well defined exudates are visible. He counts fingers correctly at the temporal side of the field.

He was under treatment at the hospital until January, 1905, when he went to Virginia. Under date of April 28, 1905, he wrote: "My vision has improved to 20/70 and has so remained for a month. I can go about fairly well and can tell a house from a cow. Yesterday I hung up the card to see what improvement had taken place. Not noticing any change I was about to accept things as they were, when I chanced to pick up a pair of field glasses; looking through them the card loomed up and I could see 20/20 as clear as a bell. I am still blind at night and have a slight amount of photopsia in the dark. There is a large floating body that crosses my field ten times a minute."

On May 11, 1905, I saw him again at my office. His vision was 20/40 and he read J. No. 1 slowly and with difficulty. Ophthalmoscopic examination showed that much absorption of the opaque material in the vitreous had taken place so that the fundus could be indistinctly seen. There were large floating masses in the vitreous. He said he had been working hard on the farm, and secreted large quantities of uric acid. When the uric acid began to diminish, the sight began to improve. The real improvement began about March 15. He had stopped all medication about a month before.

May 11, 1909. He left New York in June, 1905, and opened an office and went to work January, 1906. Worked the whole of 1906 about three hours a day. In 1907, during January and February, he took on more work, and in May commenced to do some walking. All this time there was a mass that floated over his vision. He walked up a neighboring mountain about two miles, and pretty steep, every day for one hundred consecutive days. On September 21, 1907, had as perfect vision as at any time since the trouble began. At 1:30 P. M. noticed some specks like black ink. Within five minutes only perception of light remained. Eleven weeks later he sat down in a little parlor, with only perception of light. After sitting there in a condition of abstraction for an hour, he opened his eyes and to his surprise saw a photograph across the room, and soon was able to see everything in the room just as before this period of blindness. He walked from that chair to the bathroom and was as blind as before. After that, after lying down three or four hours, would see, and on stirring around again would be blind. These periods of vision continued until June, 1908, when he opened an office again. All this time he has had "fire-works" especially at night. A white cloud often would flash up before the eye and then as suddenly subside. Exaggerated phosphenes, no pain, nor headache. Eye normal in external appearance. V=20/20—

(2 letters). Reads J 1, with + 0.75 D. Optic nerve looks healthy. Some delicate floating bodies are seen. In the vitreous, situated about midway between the optic disk and the periphery of the fundus, is a large, fixed, grayish, opaque mass, the anterior portion of which can be distinctly seen through a + 10. D. Several small blood-vessels ascend from the nasal part of the retina to this mass, while from the opposite sloping side a single, large, very dark vein runs down and becomes a retinal vein about one and a half disk diameters from the optic papilla. No retinal hemorrhage or exudation.

May 12, 1909, V = 20/20 and reads J. 1 W. + 0.75 D.

September 19, 1910, V = 20/20.

Ophthalmoscopic appearance unchanged since last examination.

This patient was presented at the New York Ophthalmological Society while his vision was at its worst. At least two members of the society had met with similar cases, in which vision had been recovered, and this encouraged us to hope for a good result. Such cases are so rare that I think they ought to be placed on record.

308 Madison Avenue.

THREE NEW PLASTIC OPERATIONS ON THE NOSE AND THROAT.*

By JOHN EDMUND MACKENTY, M.D.,

NEW YORK,

SURGEON, NOSE AND THROAT DEPARTMENT, MANHATTAN EYE, EAR, AND THROAT HOSPITAL; LECTURER ON OTOLOGY, NEW YORK POLYCLINIC POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

It is my privilege to present for consideration and judgment three new plastic operations on the nose and throat. The first is for the relief of the various obstructions of the anterior nares. The second is for the correction of septal deformities in children without sacrificing the septum. The third attempts to cure atresia of the soft palate to the nasopharyngeal wall by a surgical procedure. The work on the first and second of these covers a period of five years; on the third, of less than one year.

AN OPERATION FOR THE RELIEF OF THE VARIOUS OBSTRUCTIONS OF THE ANTERIOR NARES.

The problem of relieving obstruction in the anterior nares is constantly presenting itself to the rhinologist. Collapse of the alæ nasi has been and is the *bête noir* of this class of cases. For the sake

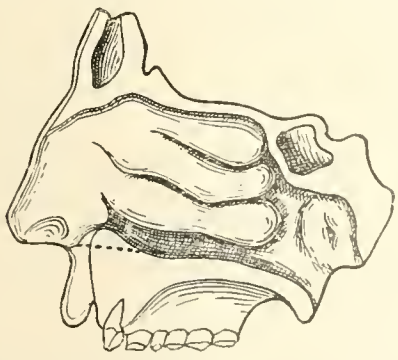

Fig. 1.

of brevity I shall not allude to the literature on this subject as it is scanty and unsatisfactory, but shall go directly to its clinical consideration. The following is what we frequently observe: (1) A narrow nose with weak, flaccid alæ. (2) Thickening of the septal base in its anterior part. (3) A great redundancy of the soft parts below and anterior to the cartilage. (4) The floor of the nostril just beyond the entrance is sometimes observed to rise from 1/8 to 1/6 of the total distance to the apex of the opening, thus forming an obstructive ridge at a right angle to the meatus. Thus from the inner and outer sides and from the floor the lumen of the nostril may be encroached upon. In the above deformities prenatal conditions combine with defective nasal breathing during the growing period to produce the picture. (5) The traumatic nose with broken down, piled up cartilage and distorted, irregular anterior floor.

The better to understand what follows, I shall give you a brief description of the anatomy bearing upon this operation. In the desiccated skull the nasal openings resemble an ace of hearts inverted. With the lower boundary of this opening we are concerned. You will observe that it presents a sickle-shaped edge, more or less sharp and more

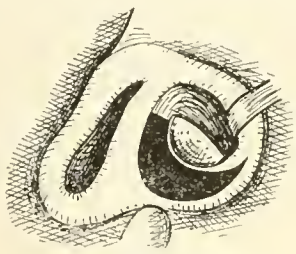

Fig. 2.

or less raised above the floor of the nasal passage behind. If the floor level behind be carried forward we find that this edge in many skulls is from ½ to 2/3 cm. above it. Now if we examine a nostril *intra vitam* we shall observe that this edge lies about 1 cm. behind the junction of the upper lip and nasal opening, and that the direction of this portion of the nostril floor inclines upward to meet at the apex of the ridge the upward inclined plane of the metal floor behind (Fig. 1). This crescentic ridge then forms the highest portion of the floor, which might be represented thus

Forward of the ridge, and on the floor and inner aspect of the nostril, are loose, areolar tissue and fat covered by skin and mucosa. The bulk of this subcutaneous tissue varies in different individuals. In some it encroaches materially upon the lumen of the opening. The lower inner boundary of the opening

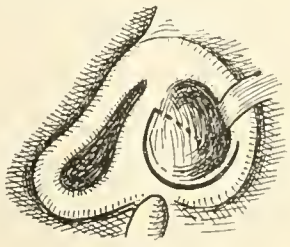

Fig. 3.

is formed by the anterior nasal spine and intermaxillary crest joined above by the quadrilateral cartilage. These are sometimes thickened and distorted and encroach upon the opening from the inner and lower margin. My operation aims to place the floor of the nasal opening on a level with or below that of the meatal floor behind, and to widen the opening at its lower and inner aspect by removing the bony ridge, part of the anterior nasal spine and

*Presented, as candidate's thesis, to the Triological Society, at Atlantic City, June, 1911.

intermaxillary crest, and all redundant soft tissue from the floor and septal side.

An incision begun well up on the septal side and a little to the skin side of the rounding edge of the nostril is carried down to and across the floor and up into the ala. (Fig. 2.) It is better to include all the subcutaneous tissue, as it strengthens the flap during the subsequent manipulation. The dissection is continued backward, using scissors and scalpel, until the ridge of bone on the floor is reached. Here the periosteum is incised and, as the dissection continues backward over the ridge, is included in the raised flap. With small chisels and Kerrison's bone forceps the bony ridge is removed over the full width of the opening and downward until the whole floor of the nasal cavity lies on the same plane. Then with a sharp, straight chisel the base of the septum (nasal spine and intermaxillary crest) is shaved down, beginning well forward and extending well back of the crescentic ridge, but the whole thickness of the septum must not be removed. Then the flap, which is quite thick in front, is thinned down by removing all the fat and areolar tissue from its under surface until nothing but the true skin and mucous membrane remain.

Now if the work has gone successfully we find that the new nasal floor lies about ½ to 2/3 cm. below the old one, and that the skin and mucous membrane flap is too short to lie upon it. In my early cases I incised the flap from before

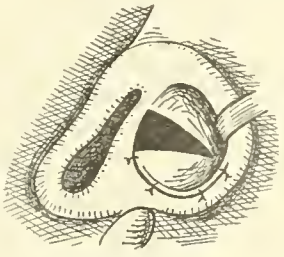

Fig. 4.

backward along the center of the floor and laid the severed portions on either side, but this brought the line of contraction in the worst possible place, so it occurred to me that by placing the bare area (necessitated by bringing the flap down to the newly made floor) on the septum a minimum amount of contraction might be secured. The flap is therefore incised (as seen in Fig. 3) as high as possible on the septal side, the incision being directed backward and downward toward the floor, which it meets at the farthest back point of denudation.

The flap is lowered to the new floor and stitched in place with fine iodized catgut (Fig. 4). Either vaseline gauze or a molded guttapercha splint, made to fit the case, holds the flap gently but firmly in position. The splint is made in the usual way by molding dental guttapercha. For these cases I cut the splint so that a flange projects forward and downward over the upper lip, to which it may be fastened by adhesive plaster. This prevents the splint slipping too far into the nose and tends to better keep the flap firmly against the new floor. A splint should be worn for ten days constantly, and then at night only for some time longer. It should be so made that its backward projection is sufficient only to hold it in place and keep the nostril well open.

This operation has been done by me on fourteen cases: For thickening of the anterior nasal floor due to fracture, in one case; for congenital high placement of the anterior nasal floor, in two cases; for encroachment on the nasal opening, from a combination of thickened septum, high nasal floor,

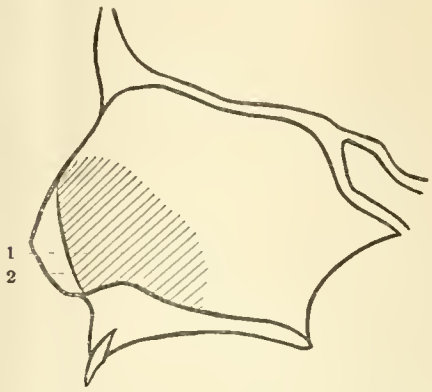

Fig. 5.—Lateral view. 1, Area of deformity. 2, Primary incision.

and redundancy of the soft parts, in three cases, and for collapse of the alæ nasi, in the remainder. The degree of alar collapse in these cases varied from a mild interference with inspiration to a marked falling in. The operation does not open the nostril over the point of collapse. It enlarges the nostril downward and inward. The current of air thus has a free access and the alæ are not sucked in on each inspiration. In this way indirectly the collapsed area above stands more open during inspiration. All the cases were much benefited by the operation.

The operation may be done under cocaine, but it is difficult to anesthetize the bone. Ten of my cases were done under general narcosis. The operation is difficult, first on account of bleeding, and second on account of the careful dissection necessary to raise the periosteum from the ridge and behind the ridge, without buttonholing it. On the integrity of the flap depends the result of the operation, since cicatricial contraction is fatal to its success.

A PLASTIC OPERATION FOR THE RELIEF OF SEPTAL DEFORMITIES IN CHILDREN.

This procedure is also applicable in adult cases where the septal deformity is so near the front that

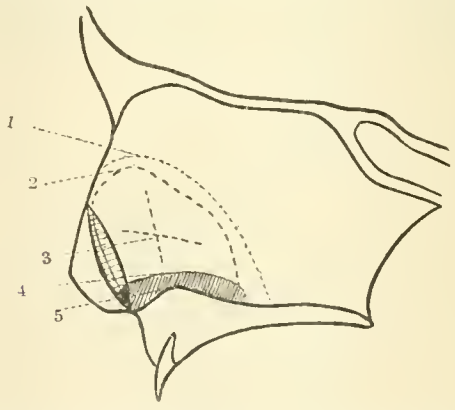

Fig. 6.—Lateral view. 1, Occasional line of incision above and behind the mucous membrane flap. 2, Line of incision through the cartilage under the mucous membrane flap. 3, Lines indicating possible angulations of deformity. 4, Anteroposterior incision through the cartilage to the distal mucous membrane. 5, Area of cartilage removed.

the ordinary submucous resection would endanger the contour of the nasal tip. It has been too much the custom to leave the septal deformities of children until about the fifteenth year before attempt-

ing their correction. Two reasons are uppermost in bringing about this delay. The first is fear of stunting the development of the nose. The second is the difficulty encountered in internasal work in

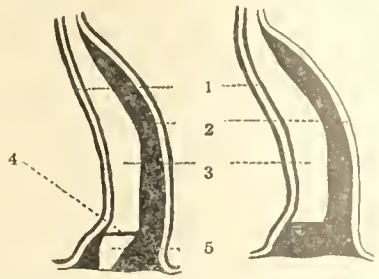

Fig. 7. Anteroposterior view. 1, Distal mucous membrane. 2, Proximal mucous membrane. 3, Deformed cartilage. 4, Anteroposterior incision through the cartilage to the distal mucous membrane. 5, Area of cartilage to be removed.

children, since the work must usually be done under general anesthesia and must, by the older methods, be followed by weeks of after-treatment on an unwilling subject. These reasons certainly do not weigh against the paramount necessity for proper nasal breathing during the developmental period of childhood. I need but hint at the long train of deformities and diseases attendant upon obstructed nasal breathing during this period, to convince you that in every case of nasal obstruction in childhood corrective treatment should be undertaken just so soon as the condition is discovered.

The type of septal deformity most commonly met with in children is a marked and angulated deviation of the cartilaginous septum. This may occupy any portion of the cartilage. I would remind you that the cartilage occupies a proportionately greater area of the septum in children than it does in adults. Here the angulation is sharp, often well forward, and may be both in the horizontal and perpendicular directions.

I would set the following requirements in any septal operation on children: (1) The removal of only sufficient cartilage or bone to allow the remainder to fit into the nasal frame without overlapping or crowding. (2) The destruction of no mucous membrane. (3) The maintenance of a perfectly straight cartilage without the necessity of splinting for more than four or five days. This means that all points of leverage should be carefully cut at the time of operation. (4) The operation should be so done as to require practically no after-treatment more irksome to the child than an occasional inspection.

All the crushing operations on the nasal septum are even more ineffective in children than they were

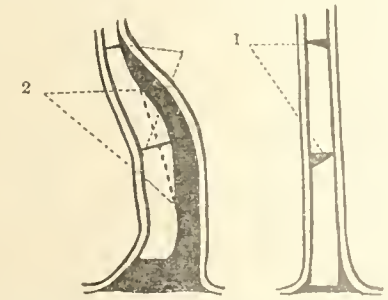

Fig. 8.—Anteroposterior view. 1, Incision in the cartilage at the lines of angulation. 2, Line of possible shaving.

in adults before the advent of the submucous resection. They are quite on a par with the gunshot prescription in medicine. The poor ultimate results and the long and irksome after-treatment urged me to try the following plastic procedure. The results when the operation was accomplished, as described below, have been satisfactory. I have observed no return of the deformity or interference with the normal development of the nose. In children under 12 years chloroform or ether anesthesia is used. Chloroform is preferred, as it engenders much less bleeding. In children over 12 and of phlegmatic temperament I have used, occasionally, local anesthesia. When general anesthesia is given bleeding adds tremendously to the difficulty of the operation. I have had in some cases a fairly dry field by packing the nose with adrenalin on cotton for 15 minutes before the anesthetic is given. In a few recent cases I have raised the flaps under cocaine anesthesia and completed the operation under ether.

The operation: An incision is made well forward of the deformity, beginning as high as possible on the septal side and extending down and across the floor to the external nasal wall. (Fig. 5.) The mucous membrane and perichondrium are then elevated all over the face of the deformity and well behind and above it. (Fig. 6.) So far the procedure is exactly the same as that used in the ordinary submucous resection. Then the cartilage is incised to the mucous membrane of the other or distal side, from before backward, the whole length of the deformity and at an elevation of

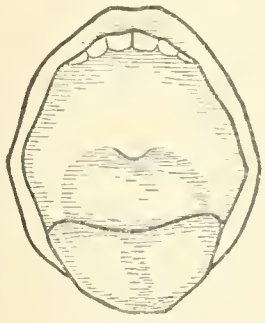

Fig. 9.

about one-quarter to one-third of an inch from the nasal floor (Figs. 6 and 7). This strip of cartilage is removed flush with the floor, taking with it the intermaxillary spine. Care must be exercised not to separate the mucous membrane from the remaining cartilage on the opposite or distal side. An angular knife is introduced under the mucous membrane flap to a point behind the deformity (proximal side) and an incision is made extending upward to the junction of the cartilage with the nasal bones, then forward along the upper border of the deformity to the tip of the nose. This incision goes to, but not through, the mucous membrane of the opposite side. Occasionally this incision is made behind and above the mucous membrane flap, thus cutting through the mucous membrane and cartilage on the proximal side wall behind and above the farthest point of denudation. This latter incision limits, to some extent, the blood supply to the flap from behind and above, but leaves it still attached to the floor, where it receives sufficient nutriment.

Now, it will be observed, we have the area of deformity separated *en masse* from the rest of the septum, being attached to it only by the mucous membrane of the opposite (distal) side and by the soft tissues at the skin margin in front of the septum. Through these two points the loosened area of cartilage receives its blood supply. This sepa-

rated plate of cartilage may now be moved over to the median line, swinging upon its upper margin as a hinge. As it swings to the center its lower margin approximates the floor, filling in partially

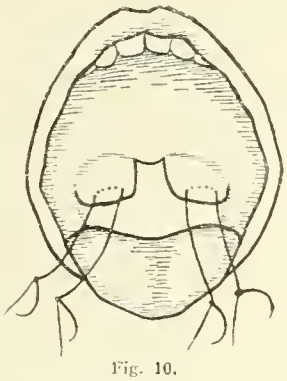

Fig. 10.

or wholly the space from which the strip of cartilage has been removed.

Often, unfortunately, the surface of the loosened cartilage occupies two or more planes, so that when brought to the center, as described above, it still, by its various angulations, does not form a perfect plane with the septum behind. (Fig. 8.) To remedy this, incisions are made at the junctions of these planes through the cartilage to the mucous membrane of the opposite side. This divides the cartilage into two or more pieces, which can then be readily adjusted so as to occupy but one plane in the central line. (Fig. 8.) The cartilage may be thinned by shaving it. The original incision in the mucous membrane is stitched. A molded gutta-percha splint is introduced on the side of the deformity and worn for four or five days. No further splinting is necessary. When the operation is properly done the cartilage should occupy the center with no tendency to revert to the old position. If any point of leverage is left uncut no amount of later splinting will prevent the deformity from partially or totally returning.

When the deformity involves the bony septum it is generally in the shape of a ridge or angular deviation extending upward and backward. To remedy this a small hole is made in the cartilage where it joins the bone. A mucous membrane elevator is introduced through the opening to the distal side and separates the mucosa from the concavity of the ridge. On the proximal side the mucous membrane is also elevated from the convexity of the ridge. The strip of bone thus exposed is removed. Then with flat bone forceps the upper and lower segments are broken over to the center line. Their

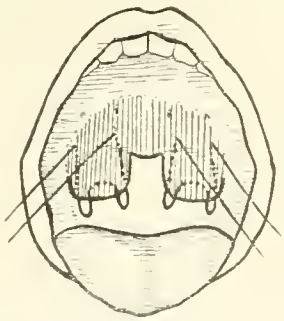

Fig. 11.—The points of emergence, a, b, c, d, should be higher than indicated in the diagram; as e, f, g, h.

convergence fills in the space formerly occupied by the bone removed, thus neither crowding nor overlapping occurs, and the septum tends to remain in the center without splinting.

I devised this operation five years ago and have done it over 100 times. The earlier cases were not all successes. In one case the loosened piece of cartilage sloughed out, but in my later cases I have had no failures. This I attribute to the greater care exercised in reducing all points of leverage by complete incision (Fig. 6) and by better conserving the blood supply to the partially severed cartilage.

A PLASTIC OPERATION FOR THE RELIEF OF ATRESIA OF THE SOFT PALATE TO THE POSTERIOR NASOPHARYNGEAL WALL.

Many procedures have been brought forward for the relief of this very obstinate deformity. The only ones that deserve mention are those of Nichols and Roe. Nichols' operation was some advance upon the older methods of divulsion and of incision with retention splints. Its principle is to cicatrize the external angles of the nasopharynx by retained silver wires or silk prior to cutting the nasopharynx open. Roe announced last year a new operation setting forth the correct principle which is to cover the posterior surface of the soft palate with a mucous membrane lining. He accomplishes this by taking a flap from either cheek and sewing them to the posterior surface of the soft palate. I did this operation on a case of syphilitic atresia with adhesions extending one-half an inch up the posterior wall. It was further

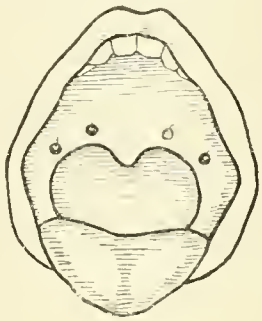

Fig. 12.

complicated by having had two former operations fail, one a simple incision and the other Nichols' wiring at the angles. The result was good. Dr. Roe, in his paper, gave the scantiest details of technique. I attempted the operation under ether anesthesia but got no further than an inspection of the field. It seems to me utterly impossible of performance except under local anesthesia. Even under local anesthesia it is so difficult a procedure that I was prompted to look about for some more simple method of procuring the necessary flaps. This led me to devise the following operation:

In all the cases of atresia that have come under my notice the mucosa covering the anterior surface of the palate is continuous with that covering the posterior pharyngeal wall. These two mucous membranes are so fused that all lines of demarcation have disappeared. On either side the pharyngeal pillars are dimly outlined, giving the lateral boundaries of the original nasopharynx. In the center we generally find a small opening, sufficient to admit a probe, leading up into the nasopharynx. With a bent probe in this opening it is possible to outline the extent upward of the atresia. (Fig. 9.) The principle of my operation is to line the posterior surface of the palate with two flaps, one for each side, taken from the posterior wall of the pharynx below the original curve of the soft palate. These flaps should be taken off as far down the pharyngeal wall as the atresia extends up the naso-

pharyngeal wall, so as to completely cover the denuded area.

The technique is quite simple. A curved needle armed with a fine silkworm gut is introduced into

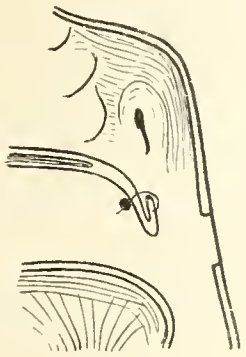

Fig. 13.

the mucous membrane of the posterior pharyngeal wall just to the outer side and about 1 to 2 cm. below the central opening mentioned above, and carried laterally to emerge at the edge of the posterior pillar. A similar stitch is taken on the other side. The points of entrance and emergence are about 1½ cm. apart. (Fig. 10.) With a sharp scalpel the flaps are now outlined, beginning at the outer side of the points of emergence of the stitches, curving downward and inward, then upward to end at the entrance of the small probe opening into the nasopharynx. Then with an angular knife or a curved scissors introduced through the opening into the nasopharynx, the atresia is separated out to the lateral pharyngeal walls and downward to the outlined flap incisions. The stitches are held as traction sutures, keeping the tissues taut while the flaps are being separated from the pharyngeal wall.

Now we will observe that the nasopharynx lies wide open and from the lower margin of the soft palate hang two flaps transfixed near their lower margins by two sutures. All that remains to do is to turn these flaps backward and upward against the raw posterior surface of the palate and stitch them in position. Four ends of sutures project from the mouth. Each end is threaded on a sharply curved needle. The needle is held in a special holder which grasps the needle parallel with the long axis of the handle. The needle is passed well up behind the palate and its point drawn forward through the palate above the raw area on the posterior surface. Similarly each of the four needles are brought through on a line with their relative places in the flap. (Fig. 11.) By drawing them taut the flaps ascend and take their positions against the posterior surface. Fine perforated shot are threaded on each suture and clamped in position near the anterior surface of the palate, care being taken to allow for considerable postoperative edema. (Figs. 12 and 13.) The contraction which takes place on the posterior pharyngeal wall, from which the flaps are taken, is negligible, since the surface is soon covered by a mucous membrane graft from the edges. The stitches are removed in four or five days. Two weeks after the operation the finger is passed into the nasopharynx. This is repeated every four or five days for a month. Then (if deemed advisable) the patient is given a dilator to use at home, to be passed by him twice a week for three or four months. This dilator is a cone set at a right angle upon a handle and made in sizes to suit the individual case. Three patients have been operated on by this method. They are all cured. The nasopharyngeal opening shows no tendency to contract.

A PRELIMINARY REPORT ON THE USE OF NEOFORMANS VACCINE IN THE TREATMENT OF CANCER.

By ALFRED POTTER, M.D.,

BROOKLYN, N. Y.

ASSISTANT ATTENDING DERMATOLOGIST TO THE KINGS COUNTY HOSPITAL.

The constant increase in the number of cases of carcinoma, and the hopelessness for a cure which we may expect from any form of treatment as yet offered makes any new remedy gladly welcomed which will either check the progress of the disease or in any way relieve the distressing symptoms and make the life of the patient more endurable. The number of cases of inoperable carcinoma in the dermatological service of the Kings County Hospital is large and in the last few years most of the better known remedies have been used to relieve the suffering and distress of these poor patients. About one year ago I received from Parke, Davis & Co., a supply of neoformans vaccine for the treatment of cancer. This remedy has been used in twelve cases with such gratifying results that they seem worthy of record.

It might be both interesting and appropriate before reporting the results to give a brief history of Doyen's *Micrococcus neoformans* and his vaccine. Doyen in 1886 sent a preliminary report to the Academy of Sciences at Paris recording his observations in malignant and other growths of small spherical mobile bodies, which he regarded as microorganisms. In 1901, in a communication to the Academy of Medicine of Paris, he corroborated his earlier findings and stated further that he had isolated by culture a microorganism from practically all new growths whether malignant or benign. This microbe was regarded by Doyen as the specific cause of cancer, as he was able by inoculation experiments on rats to produce characteristic lesions. He accordingly named the organism *Micrococcus neoformans*. Doyen sent a similar report to the Surgical Congress in Berlin in 1902. In 1904 in a second communication to the Academy of Sciences at Paris, Doyen announced the preparation of anticancerous vaccines from attenuated cultures of the *Micrococcus neoformans*. He had also prepared from toxins an antitoxin from the horse. With these measures and operative procedure combined Doyen treated 126 cases of malignant and benign growths and 21 he regarded cured. In a later report he recorded 116 cases treated, with 42 cured.

While most investigators do not acknowledge that the lesions produced by the inoculation experiments of Doyen with the *Micrococcus neoformans* are new growths and are not willing to accept his statement that the organism is the specific cause of cancer, they, nevertheless, confirm his statement that a characteristic microbe, the *Micrococcus neoformans*, can be obtained by culture from tumors. Among the first to confirm the existence of the organism was Metchnikoff and also several of Wright's fellow workers at St. Mary's Hospital, London. Jacobs and Geets, who have done an enormous amount of work in this con-

nection, after making a careful study of the subject and as a result of their own investigations, claim that all investigators, including Metchnikoff, who have sought for the organism according to methods of Doyen have found them, and the cultures of the different laboratories are identical. In their experiments they were able to cultivate the organism in 90 per cent. of cases and in 30 per cent. have produced tumors by inoculating young and vigorous cultures in mice and white rats.

The *Micrococcus neoformans* closely resembles the *Staphylococcus albus* on culture media. The two organisms take the same stain and are morphologically alike. The *Micrococcus neoformans* has a tendency to grow in bifurcating chains (Y). When a portion of cancerous tissue is placed in broth, it does not usually begin to show signs of growth for 48 hours. A well-marked growth occurring earlier than this is likely to be the staphylococcus. The colonies of *Micrococcus neoformans* die easily when growing on gelatine and do better on broth cultures. They are of white color, which they maintain even when old. They stain well with Leischmann's (Romanowski's) stain and take the Gram stain when young. The two most distinctive characteristics are the tenacious nature of the growth a few days old, which draws out in strings when taken up by the platinum loop, and the fact that it agglutinates with normal serum in a dilution of 200 to 500. This last feature distinguishes it from the staphylococcus. The cultures are most likely to be found pure in the advancing margin of a tumor or in the newly infected gland.

While Doyen claimed to have obtained good results from the use of his serum and vaccine, most observers failed to do so. Upon the publication of Wright's method of vaccine therapy, however, new interest was taken in the method by the believers in the germ theory of cancer. Jacobs and Geets claimed that the antitoxic serum of Doyen was useless and ought to be discarded as it possessed no bactericidal, bacteriolytic, agglutinating, or opsonic powers and also that the vaccine was dangerous, as it was unstandardized. They prepared their vaccine from cultures of the same age, sterilized at 60 deg. C., washed freely and standardized by the enumeration of the bacilli as advocated by Wright. They used the vaccine in 46 cases of carcinoma, with the following results: Cures maintained after several months, 7; lasting improvement, 12; transient result, 7; no result, 11; now under treatment, 9; total, 46. In every case examined by them the opsonic index to the *Micrococcus neoformans* was below normal. In all except the extreme cases where the resisting powers of the patient were beyond stimulation the opsonic index was considerably increased after the use of the vaccine. Jacobs and Geets after their experiments conclude that while it is not an absolute cure, in all cases treated there is real and definite improvement. Where the system is worn out by cancerous intoxication, improvement was only transient, but it has persisted for several months in the patients where treatment was continued. The question of success or failure seems to depend a good deal upon the reserve vital energy and capacity for reaction which each case possesses. They firmly believe that the *Micrococcus neoformans* is the specific cause of cancerous cachexia and that it is practicable to immunize the human organism by means of a series of inoculations of the *Micrococcus neoformans* vaccine when properly controlled by the opsonic index. Locally the results obtained by these two investigators are striking. The surrounding infiltration decreases, cancerous nodules are reduced to their actual size, the tumor shrinks and the skin loses its inflamed appearance. Abdominal tumors become movable and the mass can be measured. The general condition is also rapidly modified. The most striking fact observed at the beginning of the treatment is that the patient loses the cachexia, pain is diminished and the disease seems to be checked.

Sir Almroth E. Wright employed the vaccine in 5 cases. Two died, one remained stationary, and two were improved. One of the cases, an inoperable cancer of the fauces, the pharynx, the tongue and cervical glands, showed marked improvement after treatment for 10 weeks with the vaccine. Wright concludes that there can be no doubt that whatever opinions have been entertained about infection from this organism, it is a factor to be reckoned with in malignant disease. H. A. Duncan who used the vaccine with success in ten cases says that it it can be proved that the increased resistance following the use of the vaccines in cancer is specific and due to the neoformans vaccine alone, then the *Micrococcus neoformans* is a specific causative factor in malignancy. Numerous other observers have used the neoformans vaccine with successful results in the treatment of cancer.

My own observations are based on the use of the vaccines in the twelve following cases: Carcinoma of the jaw, 1; carcinoma of the esophagus, 1; carcinoma of the prostate, 1; carcinoma of the uterus, 2; carcinoma of the stomach, 1; carcinoma of the breast, 2; rodent ulcer, 3; sarcoma of the leg, 1; total, 12. All were inoperable cases and some of them in advanced stages of the disease. No opsonic index was taken on any of the cases. In three of the cases treated no appreciable effect was noticed either locally or in the relief of any of the symptoms and the patients grew steadily worse and finally died. These cases were the carcinoma of the jaw, carcinoma of the esophagus, and the sarcoma of the leg. All were advanced and hopeless cases. In the other nine cases some improvement was soon noticed, in several of the cases even after the first or second injection. The method of administration employed was to give one or two injections weekly or every three days, depending upon the length of time the positive phase lasted. The initial dose varied from 25 to 100 million microorganisms and was gradually increased to 200 million when necessary. No other therapeutic measures were used during the course of injections, and the narcotics which all the patients had been receiving in some form or other for some time prior to the injections were stopped abruptly. The most consistent effect of the treatment was the relief of pain. This effect was noticed in a greater or less degree in every case. In one case of cancer of the uterus, pain was relieved after one injection and did not return in spite of the fact that all morphine was discontinued. The general state of health in most of the patients was also much improved. They gained weight, lost their characteristic cachexia and regained their appetite and strength. When the vaccines were discontinued, patients became restless, pain returned or increased, they did not sleep and

lost their appetite and strength. If the intervals between the administration of the vaccines were prolonged, some of the patients claimed that they could feel the effect of the medicine wear off. In none of the cases of cancer of the internal organs could any diminution in size or change in the consistency of the cancer mass be noticed, but in the three cases of rodent ulcer the ulcerated area became clean, the tendency to bleeding became less, healthy granulations formed about the border of the wound and the disease seemed to be checked. In cancer of the uterus the decrease in the malodorous discharge and the bleeding was marked and lasting.

In the above series of cases treated by the neoformans vaccine, at least two of the most distressing symptoms of cancer were greatly relieved in the majority of cases, namely, pain and the cachexia. If such favorable results can be obtained in advanced and inoperable cases, it would be interesting to know what results could be obtained in early cases in conjunction with surgical procedure.

THE DROP METHOD OF ADMINISTERING ETHER.

By HAROLD A. LUCAS, M.D.,

ALBANY, N. Y.

INTERNE, ALBANY HOSPITAL.

There seems to be a question among practitioners who have frequent occasion to adminster ether as an anesthetic, not only as to the comparative merits of the open-drop and closed methods, but also as to which is the more convenient and best way of administering by the drop method. Is it better to use considerable time in preparing a gauze wick, and then still have uncertain regulation of the supply, or is it preferable to punch a hole in the top of the can with any instrument that happens to be handy, from a pin to an artery clamp, and call this the drop method? As a matter of fact the meaning of "drop method" is variously interpreted, especially by hospital internes who are frequently called upon to serve as anesthetists. For their benefit, in particular, I am offering the suggestion of a method which eliminates the objectionable features of the drop method now commonly employed, and which I believe to be new.

Cut out the top of the ether can. Fit over the rim an ordinary rubber nipple through the point of which a pin has been passed. Fix the nipple firmly in place by means of an elastic band snapped around its base. Then, by holding the can in a horizontal position, the slow issuance of drops, all of the same volume, is insured. There is no leakage, no waste, no chance of the dislodgement of a cork and a consequent deluge of ether upon the mask, or of other more or less annoying accidents which are of frequent occurrence when gauze wick and cork are used. If it becomes necessary to increase the flow of either a slight tipping of the can will produce a spray similar to that from an atomizer.

By this method patients have been kept adequately anesthetized during two hours or more, with the use of only one-half pound of ether, or even less. In cases of major operations upon babies the sight of the nipple seems to have a quieting effect, and anesthesia is produced without demonstration on the part of the subject.

I have found this method more satisfactory in results, neater, more economical, and more convenient than other methods commonly employed. Of course, the same nipple may be used repeatedly.

Treatment of Syringomyelia by X-Rays and Radium.—L. Duhain insists upon the excellent results that may be obtained in syringomyelia by means of the x-rays. The author has collected 65 cases treated by twelve or fifteen different physicians, all of whom claim good results. The hard tubes are to be used; the medulla is irradiated obliquely, the tube being placed aside from the median line, the rays traversing only the sides of the vertebral arches, and the application can be made alternately on the opposite sides of the column. The lesions are somewhat less extensive than the clinical manifestations would lead us to believe, and a wide application of the rays will prevent the extension of the process. There is a marked improvement of the motor symptoms, so that the patient is able to take up again an active life. The exaggerated reflexes diminish; there is a modification of the sensory symptoms to a less degree; anethesia improves first, then pain sense and thermic preception; the deep sensibility and the stereogenetic sense improve more slowly. Vasomotor and trophic sense also improve, the ulcerations heal, circulation is re-established and edema disappears.—*Annali di Electricità Medica e Terapia Fisica.*

Unexpected Dangers of Whooping-Cough.—Rousseau-Saint-Philippe calls the attention of parents and physicians to the abortive cases of whooping-cough which make of the little patients unwilling bearers of the disease. There are two common errors with reference to the disease; that it is a simple disease and that the diagnosis is to be made only by the whoop. There are many cases in which we get a paroxysmal, spasmodic cough without the typical whoop, and yet in which the microorganism discovered by Bordet and Gengou is to be found. As soon as the diagnosis is made isolation should be careful, both to prevent the spread of the disease and to prevent the little sufferer from acquiring further infections. It is a fact that a simultaneous epidemic of measles causes the mortality of whooping-cough to be greater. These children should be carefully excluded from school and from clinics for children. There should be a special clinic for them. The complications of this disease are many and serious; acute, and subacute bronchopneumonia, bronchitis, pulmonary congestion, bronchiectasis, emphysema, and enlarged bronchial glands. Tuberculosis may be the result of the cachectic state into which the child falls. Whooping-cough is really one of the most fatal of diseases among children.—*Journal de Médecine de Bordeaux.*

Exophthalmic Goiter in a Boy of Ten.—W. E. Wynter reports the case of a boy who exhibited undue prominence of the eyes at the age of 10, nearly a year ago. When admitted to the hospital there was obvious proptosis, with all the usual signs. The thyroid gland was enlarged, both isthmus and lobes; the fingers, when extended, exhibited fine tremor; the skin was moist and flushed, and about the hands and neck showed yellowish pigmentation. There had been no cramps, but the patient had faint attacks, flushes and occasionally showed temporary puffiness of the face. There was incontinence of urine, which contained a trace of albumin. The pulse ranged from 92 to 124. Thyroideetin was given in five-grain doses twice a day. On two occasions pituitrin was substituted, but the pulse rose to 110 and 124 under its influence, falling to 96 when it was discontinued. The case was a mild one, but exceptional on account of the sex and age of the patient.—*Proceedings of the Royal Society of Medicine.*

New York, November 25, 1911.

A NEW REACTION FOR SYPHILIS.

ALTHOUGH Schereschewsky about two years ago demonstrated the possibility of cultivating the *Treponema pallidum*, nevertheless the cultures that he obtained were contaminated with bacteria. It remained for H. Noguchi, who reported his results in the *Journal of Experimental Medicine*, August 1, 1911, to succeed in cultivating this microorganism in a pure state, and also to complete the chain of evidence that it is the pathogenic agent in syphilis. It was with difficulty that the *Treponema pallidum* could be subjected to cultivation, and, furthermore, this was possible only with certain strains of the parasite. With the use of a culture medium consisting of serum water containing a piece of sterile rabbit tissue and under strict anaerobic conditions, Noguchi obtained initial generations of the above strains, from one of which twenty-five generations of subcultures have been derived.

Important as was this triumph of patient investigation, it was but the prelude to a discovery that bids fair to mark another epoch in the history of syphilology. At a meeting of the Williamsburg Medical Society, held November 13, 1911, Noguchi announced that he had obtained a cutaneous reaction in the diagnosis of syphilis. This reaction, which may be compared to the von Pirquet test in the diagnosis of tuberculosis, is dependent upon the condition of allergy or of anaphylaxis resulting from infection with the microorganism of syphilis. The increased susceptibility of the skin to the syphilitic virus, although it had been demonstrated by others who resorted to cutaneous inoculations with syphilitic tissues, nevertheless was first established by Noguchi through the use of inoculations with material obtained from the isolated microorganisms. Sterile suspensions of these were prepared by Noguchi and designated "luetin." This was employed in two series of experiments: on syphilitic rabbits and on human beings. Of the latter about 400 were experimented upon, including, besides about 50 normal individuals, 100 who were suffering from various non-syphilitic diseases; the remainder were cases of syphilis in its various stages. The "luetin" was administered by means of cutaneous injections of 0.05 c.c. In the normal and non-syphilitic cases there was no reaction beyond that resulting from the traumatism of inoculation. In all of the tertiary cases of syphilis in which there were manifest lesions there was a positive reaction consisting of induration, erythema, and finally pustulation. Even tertiary cases, which had been treated regularly with mercury or with salvarsan and which presented no manifest lesions, in nearly all instances gave a markedly positive reaction, although the Wassermann reaction was either weak or negative. In cases of primary syphilis the reaction was almost invariably negative, which was explained by the fact that cutaneous anaphylaxis had not yet developed. In secondary syphilis the positive reaction was obtained in more than one-half of the cases that had been treated with mercury, and in more than two-thirds of the cases that had been treated with salvarsan. Some of the cases that gave a negative cutaneous reaction also gave a negative Wassermann test. Ninety per cent. of the cases of hereditary syphilis showed a markedly positive cutaneous reaction, which was also the case with instances of latent syphilis, in which neither symptoms nor a Wassermann reaction were present. Parasyphilitic affections gave much less constant results.

The results of the cutaneous inoculations in the human cases were closely paralleled by those obtained by similar inoculations in the rabbit. When recently infected with syphilis these animals did not respond by means of a positive reaction. It was only after the condition of cutaneous anaphylaxis had been developed as the result of successive inoculation over a period of five months with virulent syphilitic material that the rabbits gave a positive response to the cutaneous injection of "luetin."

Of great significance is the fact that the anaphylactic reaction may exist even though the Wassermann reaction may be negative. This imparts to the former a decided value, particularly in the diagnosis of tertiary cases, in which the symptoms may be obscure, and in latent and inherited syphilis. In primary syphilis the absence of the anaphylactic reaction and its variability in secondary cases restrict its utility to the cases of tertiary syphilis and those of the inherited disease. These are, however, particularly the cases in which a ready means of diagnosis is desirable. If further experience proves that the cutaneous reaction is a reliable one, it will place in the hands of the general practitioner a ready means of diagnosis, at any rate of tertiary and hereditary syphilis. In technique the simplicity of the cutaneous reaction forms a sharp contrast to the complexity of the Wassermann test. The latter will, nevertheless, still retain its prestige in the diagnosis of primary and secondary syphilis.

THE NEED OF EXERCISE BY SCHOOL GIRLS.

IT is a fact too obvious to need more than mention that many school children, like most college students, fail to get a sufficient quantity of regular physical exercise, with the result that present health and, to a greater extent, future prospects suffer. They live, to state it in physiological terms, on a lower plane of metabolic efficiency than is wise or even safe. This condition applies to boys much less than to girls, of course, but even they, as

every good city schoolmaster will complain, frequently desire exemption from the prescribed school athletics, in whatever form they may be arranged. It is, however, with the girls that we are chiefly concerned here, and especially with young adolescent girls of the grammar and high-school grades.

We may for our present purpose divide these girls (in years from nine, say, to fifteen or more) into three classes, each frequently visible in every school of any size: The unfit, the lazy, and the pseudo-unfit—unfit, that is, for the required exercise. With the really unfit we are not concerned here, and need pause at them only to suggest that it is a rare occurrence for a child to be really harmed by the carefully supervising instruction of the city schools of the present day, and surely a still rarer occurrence in the best private institutions. With the relatively uncommon instances in which true laziness is the cause of the desire to avoid athletics we are, on the other hand, concerned. These children usually need above all things else a habit of necessary exertion with their muscles, "the master tissues of the body," as Foster called them, the means of all accomplishments, one way or another, worthy of human effort. Some of these children actually have never experienced the substantial pleasures of physical exertion or the deep enjoyment of rest after it. And the automobiles and trolley cars are making the matter ever worse.

The third class of children who ask for exemption from required athletics is the most numerous class and the hardest to deal with—the "pseudo-unfit" we have called them, although the "neurotics" would be usually as appropriate a term. These girls, it is important to observe, are precisely the ones who need systematic physical training most, yet they are the children who most often cajole their mothers or other guardians into obtaining exemption for them. As every physician knows, overeating and undersleeping plus underexercise are the chief causal factors in this condition in rapidly growing children, but, as every physician ought to keep in mind also, if the girls get abundant exercise, the other two correct themselves. Some girls, many, in fact, come into the world with a neurological handicap, and these need, above all, whatever of correction systematic training, physical and moral, and well-devised and supervised athletics can give them—and often this is very much. Turn back to Charles Reade and Thackeray and Dickens and see in the girls of two generations since a notion of what our girls to-day might be without the renaissance of physical outdoor life! The days of "prunes, prisms, and persimmons" are, happily, mostly gone—they linger only in these neurotic girls about whom we speak.

Many physicians still are ignorant of the high plane of most of the work done to-day in the gymnasia, the playgrounds, and the athletic fields, and most of them, it is safe to say, utterly underestimate the basal anatomic and hygienic knowledge put in practice by the instructors in these places. The gymnastic and playground work in schools is of vast value as now systematized and directed, and, with the rise of sexual hygiene, is rapidly becoming still more useful and efficient in the very basis of happy womanly life. Instructors in athletics are nowadays, as a rule, competent to handle the children in their care, and are usually graduates of elaborate schools where physiology, hygiene, spinal conditions, psychology, etc., are scientifically and practically taught. The result is that very many of these instructors now know more about such conditions and are actually better judges of what is good or bad for a child than the average family physician.

As an illustration of actual conditions we may quote from a report by Miss McKinstry of experience in one of the Brookline, Mass., public schools. One year out of 216 students 45 presented certificates from physicians and were excused to the number of 11. Reform was declared in this respect, and the next year in a class of 301 none presented certificates and 12 were excused. Here is argument in two directions too obvious to need rehearsing. It certainly is to-day a professional duty owed by physicians to their own patients as well as to the general good to refuse to cater to the whims or misinformation of parents or guardians regarding the physical exercise of their children.

THE SALIENT EPIDEMIOLOGICAL FEATURES OF PELLAGRA.

The most significant feature of present-day research is the manner in which investigators are delving into the etiology of various diseases, perhaps mainly from the bacteriological standpoint. Long-held views with regard to the origin of many maladies have been subjected to revision. Pellagra is one of the diseases of which the causative agent is now being keenly looked into. The old theory that it is a disease of diet and that its manifestations are chiefly due to maize poisoning has been subjected to sharp criticism of late and it now appears probable that the time-honored views in this instance will have to undergo a considerable amount of revision.

In *Public Health Reports* of September 29, 1911, Passed Assistant Surgeon C. H. Lavinder, United States Public Health and Marine-Hospital Service, contributed a timely review of the situation as regards the epidemiology of pellagra. In the first place he points out the value to be attached to epidemiological studies as an aid in the elucidation of the etiology of disease and draws attention to the fact that such studies are lacking for pellagra. Indeed, the work of this kind is restricted to that of Sambon and Allesandrini. Although both of these authors have made important contributions to the subject, the value of these is largely discounted because each is striving to establish his own hypothesis of the etiology of the disease. Moreover, as Lavinder aptly shows, the studies of these two authors were made exclusively in Italy and practically all recorded epidemiological observations refer, if not to Italian pellagra, at least to the pellagra of southern Europe. Observations are lacking for many places where the disease is known to be endemic and there are none for the United States.

The need for widespread studies of this nature is obvious, and the object of Lavinder's paper is to remedy to some extent this lack.

At present the disease is probably most prevalent in Northern and Central Italy, Southern Roumania, the Austrian Tyrol, Southeast Hungary, and the Southeast United States. Perhaps Lower Egypt might be included. In a general way it may be said that pellagra is confined to tropical and subtropical regions. Its local geographical distribution presents very striking peculiarities. It appears to confine itself in Italy to particular regions, while neighboring places, without any definite apparent cause, are exempt. Such sharp limitations, however, are not constant. From Roumania it has apparently invaded neighboring parts of Russia and of Austro-Hungary. In the opinion of most observers the topographical distribution of the disease has furnished no facts of importance. But Sambon, in support of his simulium theory of the spread of pellagra, places great stress on topographical distribution. This forms an essential point in his hypothesis. His observations go to show that the disease is ilnked to the swiftly running streams in which the simulium breeds.

A very striking fact in connection with European pellagra is that it is essentially a rural disease. Men with most experience on this side, on the contrary, believe that the small mill towns and villages in the Southern United States suffer most from the disease. In Europe, too, where it has always been termed "the disease of misery," the great majority of those who suffer from it have a poor food supply. Again, in the United States, this does not seem to be a marked feature of the disease. Pellegra occurs at all ages, even the infant at the breast being included. With regard to sex incidence, in Europe women are somewhat more frequently affected than men, and in this country the preponderance of females is marked. Race or nationality is more or less a negligible quantity. As to occupation, in Europe the agricultural laborer is the chief sufferer, while here this is not the case. Heredity plays a part in that a predisposition to the disease may be inherited. It is the general belief that the disease is not communicable in any sense whatever. Yet several observers in the United States have raised again the question of contagion and affirmed a belief in its probability. Pellagra may be classed as endemic, at times epidemic, but never pandemic. The disease appears to present the characteristics of a "place infection" in the sense in which the expression has been used with regard to beriberi. The seasonal incidence of pellagra is one of its best known and most strongly marked characteristics.

So far as clinical characteristics are concerned pellagra is a general disease of marked chronicity with periodical exacerbations of a peculiar kind; also with the intervention at times of certain very striking attacks of a fulminating nature. With regard to its inception and evolution there is no agreement. But it may be said, from both clinical and pathological data, that the morbid process displays its most marked and most essential effects on the central nervous system. Further, pellagra is in a sense a secondary disease, a morbid process which so to speak engrafts itself upon some preceding morbid condition or depressed state. The disease displays more virulence by far in the United States than in Europe, a fact to be explained, perhaps, to some extent by the development of a partial immunity to pellagra in those countries in which it has been long prevalent. Lavinder shows that there are many well authenticated cases of undoubted pellagra which have had no connection with maize. Such cases are sporadic. The question has been also asked, is pellagra a morbid entity or may there be included under this term more than one morbid entity? Lavinder deems it a morbid entity.

The etiology of pellagra and that of beriberi appear to possess many points in common. It has virtually been proven that beriberi is due to an insufficiency of phosphorus content in the diet, caused by the consumption of polished rice. Simpson and Edie, writing in the *Annals of Tropical Medicine and Parasitology*, published by the School of Tropical Medicine of the University of Liverpool in August last, point out, as a result of their experiments of feeding pigeons with bread made from wheat from which the husk had been removed, that a whole cycle of diseases in all probability have a similar etiology to that of beriberi. Among these they include pellagra. Up to the present time, despite the many strong points brought forward by Sambon in support of his theory, the "zeists" still have many plausible arguments on their side.

Saving the Hundredth Man.

In an article with this title in *Surgery, Gynecology, and Obstetrics* for October W. P. Carr writes concerning the need for greater care in the details of surgical operations. It is pointed out that up to recent times sepsis easily led the list causes of death in operations, with hemorrhage and shock next in frequency. But as hemorrhage and sepsis were practically mastered, surgeons began to recognize more fully the dangers of anesthesia, of renal insufficiency, of gastric dilatation, of adynamic ileus, of myocarditis and atheroma, of complicating diseases in general, and of shock which is caused by complicating disease or intensified by it. Carr shows that the essential factor for securing good results is not to operate, except in cases in which prompt procedure is necessary to save life, until the patient has been brought into as ideal a condition as may be. He also lays stress on the importance of the patient being in a hopeful frame of mind prior to operation and argues that every step should be taken to avoid alarming him. For instance, to chat with a patient in a cheerful manner does much good, and he advises against following a common practice in some hospitals of carrying a patient upon a stretcher to the anesthetizing room and allowing him to remain there fifteen or twenty minutes or even longer, practically unnoticed, while waiting for some one to give ether, or for the operator to arrive. In order to save the hundredth man, Carr says, more attention must be paid to the following things: (1) A careful study of our patients and a careful endeavor to get them into as nearly an ideal condition as possible. (2) Avoidance of preoperative shock. (3) Diminishing operative shock by (*a*) skilful anesthesia, (*b*) shortening the

time of anesthesia and operation, (c) avoiding rough or prolonged handling of viscera and important nerves. (4) Rapid work will be greatly facilitated by knowing beforehand just what is to be done and doing it, not hurriedly, but without hitch or delay, sharp knives, scissors, and needles, and all necessary instruments being always ready. (5) Leaving wounds in ideal condition is of more importance than is generally believed. (6) Gloves should not be used in cases in which clean, rapid work is of paramount importance.

The Control of Rabies.

According to the bulletin of the Department of Health of the City of New York for September, 1911, reports from the Research Laboratory and from the Division of Contagious Diseases of the department indicate that rabies is gradually increasing in prevalence in the city. The bulletin points out the potent fact that from the broad standpoints of the health of the city and efficient public housekeeping, the existence of the disease is a growing municipal disgrace. In England rabies has been completely stamped out and prevented from reappearing by an effective system of detention and quarantine of all dogs brought into the country. The present control of the situation as regards the disease in this country, however, is inadequate. The bulletin sketches the essential features of municipal surveillance. Foremost of the measures calculated to abolish rabies is an ordinance requiring that dogs at large be permanently either muzzled or leashed. It was by such means that the disease was stamped out in England, Germany, and Denmark. An important factor also is education in regard to the care and observation of dogs by their owners. An adequate system of licensing by the municipal authorities may also have an important, although indirect, effect in the reduction of the number of stray dogs. The bulletin draws attention to the fact that among all the communities which have taken definite action in this respect, New York is the only city, of which the department has knowledge, in which the licensing of dogs is not a function of the municipal government. The statistics included in the bulletin may be commended as worthy of perusal by citizens of New York who are jealous of her good name in matters concerning the public health. In Greater New York in 1910 the number of dog bites reported and investigated by the Division of Contagious Diseases was 3,792, and during the first six months of this year 2,105. The Department of Health does all in its power to cope with the existing state of affairs, but laws are required whereby an adequate plan of control may be instituted by which the disease may be eradicated. This has been accomplished in other countries and can be accomplished here.

News of the Week.

New York's Death Rate.—Statistics from the Department of Health for the week ending November 18, 1911, show that the death rate was 13.44 per 1,000 population, as against 13.73 for the corresponding week of last year. Typhoid fever, pneumonia, intestinal diseases, and nephritis showed a falling off in mortality, while heart disease, consumption, and deaths from violence showed a gain. There was a slight increase in the number of deaths of children under five years of age.

Smallpox in Brooklyn.—Two cases of smallpox have been reported in Brooklyn; these are the first that have been brought to the attention of the health authorities in two years.

Smallpox in Pawtuxet Valley.—The State Board of Rhode Island scores the public school teachers of Pawtuxet Valley for permitting unvaccinated children to attend school and blames this laxity for the epidemic of smallpox in that vicinity. It is stated that of all those who have had smallpox not one had been vaccinated.

Plague in the Mediterranean.—A dispatch to *The Sun* states that the members of the Superior Council of Health of France have been hastily summoned to Toulon to investigate cases of bubonic plague. The Mediterranean fleet and the Colonial Office have been notified that there is bubonic plague at Philippeville, Algeria, where seven cases have proved fatal.

Glanders in Boston.—The persistent increase of glanders among the horses in and about Boston has been the occasion of considerable anxiety and the cooperation of the Board of Health has been asked in combating the disease. Dr. S. H. Durgin, President of the Board of Health, is advocating legislation to prevent horses afflicted with the disease from entering the State and for providing adequate compensation for the owners when it becomes necessary to kill animals on account of the disease.

A Conference on Pellagra.—Dr. J. A. Haynes, Health Officer of the State of South Carolina, called a conference of the health officers of the State on November 2 to which all physicians were invited to bring cases of pellagra. The public was invited to be present at both the scientific meeting and the clinic.

One Death a Day by Fire.—The City Committee of Safety, appointed to inquire into the conditions in loft and factory buildings, reports them as bad as before the Triangle waist factory fire last year. The report states that there is an average of one person a day burned to death in New York City.

Commercial Congress Discusses Public Health.—The Trans-Mississippi Commercial Congress which met in Kansas City on November 14 and which in other years has considered such problems as irrigation, waterways development, postal saving banks, etc., devoted its attention to questions bearing on the conservation of public health. It will make recommendations to Congress regarding plans for the proposed federal department of health.

Sanatorium for Locomotor Ataxia.—Through the generosity of a Chicago business man a sanatorium has been opened for the treatment of locomotor ataxia patients free of charge. Dr. Herman Silverman of Berlin will conduct the clinics.

National Educational Association Urges Health Work.—The Department of School Patrons of the National Educational Association has mailed letters and data to all parts of the country urging clubs to take up the work of improving health conditions in the schools. It has outlined methods of procedure as regards investigations and suggests subjects for discussion.

Missouri Preparing a New Hospital Bill.—Following the investigations of the hospitals of St. Louis by a Special Investigating Committee, a bill

is being prepared for presentation to the Legislature, the unusual feature of which is that it proposes three resident physicians for a hospital who shall be on duty in eight-hour shifts.

Lying-In Hospitals Closed.—The inspector for lying-in hospitals for the State of Colorado has closed six maternity homes in Denver, while only four lying-in institutions received his approval. It is said that those who have been refused a license are going into court to test the power of the State Board to take away their licenses.

The Webber Hospital at Biddeford, Me., which was erected at a cost of $100,000, was formally opened on November 8. It is built of brick and reinforced by concrete and there is practically no wood about the building.

Glass Eyes Captured.—Government agents recently seized 2,400 artificial eyes in Baltimore, alleged to be part of a lot of about 100,000 smuggled into the country by a man in Hoboken.

Honor Aged Physician.—The Whiteside County Medical Society held a special meeting on November 9 in honor of Dr. Charles A. Griswold, who is 86 years of age and the oldest physician in the county. Dr. Griswold was graduated from the College of Physicians and Surgeons of New York City in 1856 and has been practising in Fulton, Ill., for fifty-five years.

The Deaconess Hospital at Concord, N. H., was dedicated on November 12. The hospital is the gift of Charles Emerson, a cousin of Ralph Waldo Emerson.

Dr. Cleveland H. Shutt has been elected Hospital Commissioner of St. Louis.

Christian Scientists Barred from Canal Zone.—A few weeks ago President Taft gave an order requiring all persons except Government physicians who wish to practise medicine on the Isthmus to obtain a license from the Board of Health of the Canal Zone. Hitherto Christian Scientists have declined to apply to medical boards for licenses and unless they change their custom they may be liable to fine and imprisonment for violation of the executive order, unless this order is modified.

Plan to Enlarge Kingston Hospital.—The governors of this hospital have appointed a committee to secure funds and plans for enlarging this institution, which has just completed its most successful year and is greatly in need of larger facilities.

Attempt to End Fee-Splitting.—The Medical Society of Jackson County, Kansas, at its meeting on November 7, passed resolutions designed to put an end to fee-splitting; any member found guilty of the practice will be expelled.

Chicago Schools Teach Little Mothers.—Hereafter one room in each public school building in Chicago will be used for the instruction of girls in the care of babies. The Board of Health of the city supervises the work and furnishes the equipment.

Lepers in Philadelphia.—Two women who are suffering from leprosy have been discovered in Philadelphia; both have been removed to the isolation wards of the Philadelphia Hospital and their homes quarantined.

Tufts College Instructors Quit.—Following the resignation of Dr. David D. Scannell, assistant professor of surgery at Tufts Medical School, all of the instructors in surgery and also the assistant professors and instructors in the department of pediatrics have sent in their resignation. The difficulty which led to this step is said to have had its inception in certain appointments made when Tufts College secured control of the Grace Emergency Hospital.

Immunization Against Pneumonia.—It is stated in the *British Medical Journal* that Sir Almroth Wright has been commissioned by the mining groups of the Rand to investigate and report on the question of immunization against pneumonia, a disease which is said to be the cause of the largest mortality among the native laborers on the goldfields.

Cerebral Congestion at Cornell.—Complaint is made that there are too many, if not too much, brains at Cornell University. For many years Prof. Burt G. Wilder has received and examined brains of celebrated persons, and others sent to him. Since his retirement from active work, however, the brains have been received more rapidly than they could be examined, and the receptacles containing them are filling up the museum to the inconvenience of many students.

The Barnes Medical College in St. Louis has ceased to exist, having incorporated into the American Medical College, losing thereby its name and identity, although the new institution will occupy the buildings of the Barnes University.

The Central Illinois District Medical Society, which met in semi-annual session at Pana, on October 31, elected the following officers: *President*, Dr. M. P. Parrish, Decatur; *Vice-President*, Dr. Louis Miller, Pana; *Secretary*, Dr. J. N. Nelma, Taylorville; *Treasurer*, Dr. Walter Burgess, Pana.

A New Tri-State Medical Association Organized.—At a meeting of the Florida State Medical Association of colored physicians, dentists, and pharmacists it was decided to organize a Tri-State Medical Association formed of delegates from Georgia, Florida, and Alabama. The following officers were elected: *President*, Dr. J. Seth Hills, Jacksonville; *Secretary*, Dr. L. B. Palmer, Atlanta, Ga.; *Treasurer*, Dr. A. M. Broen, Birmingham, Ala. This organization will hold its first meeting in Jacksonville on February 1, 2, and 3, 1912.

The American Institute of Homeopathy has elected the following officers: *President*, Dr. T. H. Carmichael, Philadelphia; *Vice-Presidents*, Drs. W. H. Dieffenbach of New York and Clara Emerette Gary of Boston, Mass.; *Secretary*, Dr. J. Richey Horner of Cleveland; *Treasurer*, Dr. T. F. Smith of New York; *Honorary President*, Dr. G. B. Peck of Providence, R. I.

The Southern Illinois Medical Association, at its thirty-seventh annual session held in Mount Vernon on November 3 and 4, elected the following officers: *President*, Dr. Andy Hall of Mount Vernon; *Vice-Presidents*, Drs. H. E. Wilson of Centralia and W. E. Lingle of Cobden; *Secretary*, Dr. C. W. Lillie of East St. Louis; *Treasurer*, Dr. J. W. Armstrong of Centralia.

The Central Illinois Homeopathic Medical Association at its thirtieth annual meeting, held on October 26, elected the following officers: *President*, Dr. J. W. Calvert, Dwight; *Vice-President*, Dr. Calvin A. Frazee, Springfield; *Secretary-Treasurer*, Dr. Lewis T. Roades, Lincoln.

The New York and New England Association of Railway Surgeons, who held their twenty-first annual meeting at the Hotel Astor in New York City on November 16, elected the following officers, *President*, Dr. Walter Lathrop, Hazleton, Pa.;

Vice-Preisdents, Drs. J. W. Le Sen of Batavia, N. Y., and C. A. Pease of Burlington, Vt.; *Secretary,* Dr. George Chaffee of Brooklyn, N. Y.; *Recording Secretary,* Dr. J. H. Reid of Troy, N. Y.; *Treasurer,* Dr. J. K. Stockwell of Oswego, N. Y.

The Homeopathic Medical Society of Oregon at its annual convention in Portland on October 25 elected the following officers: *President,* Dr. John F. Beaumont, Portland; *Vice-Presidents,* Drs. J. S. Bishop of Forest Grove and A. J. Fawcett of Ashland; *Secretary,* Dr. J. F. Worcester; *Treasurer,* Dr. Charles Billington of Portland.

Kentucky State Medical Society.—At the fifty-sixth annual meeting of this society, held in Paducah on October 25 and 26 the following officers were elected: *President,* Dr. D. O. Hancock of Henderson; *Vice-Presidents,* Drs. Delia Caldwell of Paducah, W. L. Mosby of Bardwell, and J. R. Steele of Corbin; *Secretary,* Dr. A. T. McCormack of Bowling Green; *Treasurer,* Dr. W. B. McClure of Lexington.

The Medical Society of the County of New York will hold its 106th annual meeting on Monday evening, November 27, at which time officers will be elected for the ensuing year.

Obituary Notes.—Dr. Henry C. Dalton died at the Deaconess Hospital, St. Louis, Mo., on November 3, following an operation for appendicitis. Dr. Dalton was 65 years of age and was a graduate of the Missouri Medical College in 1870. He was professor of abdominal surgery and clinical surgery at Marion Sims College of Medicine, and more recently instructor of surgery in the St. Louis University.

Dr. John H. Hollister of Chicago, Ill., a graduate of Berkshire Medical College, Pittsfield, Mass., in 1847, died at Redlands, Cal., November 13, at the age of 89. For many years he was a prominent physician in Chicago and active in the work of the American Medical Association.

Dr. Andrew J. Mayfield of Campbell, Mo., died of apoplexy November 11 at the age of 66 years. He was a graduate of the College of Physicians and Surgeons, St. Louis, Mo., in 1885.

Dr. Wooten M. Wilkerson, a graduate of New York University Medical College in 1880, died in Montgomery, Ala., October 27, aged 53.

Dr. Alfred Cochran Lambdin, a graduate of the University of Pennsylvania, Department of Medicine, in 1866, died suddenly of heart disease at his home in Philadelphia, November 7, aged 65. He was editor-in-chief of the *Public Ledger* and noted as a music and dramatic critic and writer.

Dr. Charles W. M. Brown, a graduate of the Medical School of Harvard, Boston, in 1876, a member of the Medical Society of the State of New York, the American Medical Association, Academy of Medicine, consulting physician Arnot-Ogden Memorial Hospital, died at the Arnot-Ogden Memorial Hospital, October 29, aged 63.

Dr. Anthony F. Vadeboncœur, a graduate of Syracuse Medical College, New York, in 1877, a member of the Medical Society of the State of New York, died at his home in Syracuse, N. Y., November 9, aged 57.

Dr. Thomas H. McGann of Gloversville, N. Y., died November 8 of myocarditis. He was a graduate of Dartmouth Medical College in 1876. He was a member of the Medical Society of the State of New York and of the Johnstown and Gloversville Medical Associations.

Dr. Richard M. Wyckoff died at his home in Brooklyn, November 11, at the age of 73 years. He was a graduate of Bellevue Hospital Medical College in 1864.

Dr. William B. Martin of Sherrard, Ill., a graduate of Rush Medical College in 1888, died at his home on November 3, aged 51 years.

Dr. Frank W. Graham of Luddington, Mich., dropped dead on the street from heart disease on November 4. He was born in 1856 and was graduated from the St. Louis College of Physicians and Surgeons in 1883. Dr. Graham served as Mayor of Luddington for four consecutive terms and was City Health Officer for two years.

Dr. John A. Hillsman died at his home in Richmond, Va., on November 5, after a long illness. He was 78 years of age and was graduated from the University of Pennsylvania in 1859. He was born in Amelia County and moved to Richmond about twenty years ago. He was a Confederate Veteran, having been connected with the Forty-fourth Virginia regiment and having served as surgeon to Pickett's camp.

Dr. David C. Coleman died at the Beverly Hospital of general peritonitis, following an operation for appendicitis on November 5, at the age of 32. He was a graduate from the University of Georgetown in 1904 and had been city physician of Beverly, Mass., for five years.

Dr. John F. Bransford died at his home in Bon Air, Va., on November 5. He served in the Confederate Army and later became a surgeon in the United States Navy. He was retired after the Spanish-American War by special act of Congress with the thanks of Congress and a medal for bravery.

Passed Assistant Surgeon Ransom E. Rigg died on board the battleship *Ohio* November 17. He was born in Berkeley, S. C., 38 years ago.

Dr. Richard Morris Wyckoff of Brooklyn, N. Y., died of angina pectoris on November 11 at the age of 73 years. He was graduated from Amherst College in 1859 and from Bellevue Hospital Medical College in 1864. He was an assistant surgeon in the United States Navy during the last year of the Civil War, served in the Department of Health in the old city of Brooklyn under several administrations. In 1894 he became Sanitary Superintendent of Brooklyn and Deputy Health Commissioner. He was secretary of the Kings County Medical Society for many years, was one of the founders of the Medical Society of the State of New York and the New York Medico-Historic Society, and a contributor to many medical publications.

Dr. George W. Winterburn died at the New York Hospital November 18 at the age of 66. His death was attributed to apoplexy. He was a contributor to many medical magazines.

Dr. Albert A. Ames of Minneapolis, Minn., died suddenly on November 16 at the age of 69. For many years he was Mayor of Minneapolis and at one time a candidate for Governor of the State.

Dr. John J. McAvoy, a graduate of Bellevue Hospital Medical College in 1895, died at his home in Lawrence, Mass., on November 12.

Dr. G. A. Brug of Providence, R. I., a graduate of Bowdoin College in 1875, died at his summer home in Chilmark, Mass., on November 12 at the age of 58 years.

Dr. L. M. Bassett died at his home in Hearne, Tex., on November 8.

Obituary.

SURGEON-GENERAL WALTER WYMAN, M.D., LL.D.

U. S. PUBLIC HEALTH AND MARINE-HOSPITAL SERVICE.

Dr. Walter Wyman, for twenty years head of Marine-Hospital Service, died in the Providence Hospital, Washington, on November 21, from a carbuncle of the face for which he had been under treatment for several weeks. He was born in St. Louis August 17, 1848, was graduated in arts from Amherst College in 1870, and in medicine from the St. Louis Medical College in 1873. He entered the Marine-Hospital Service in 1876 and was appointed supervising surgeon-general in 1891. On July 1, 1902, when the service was enlarged and was called the Public Health and Marine-Hospital Service, he was continued at its head with the title of surgeon-general. During his long connection with the service, and especially after his elevation to the office of surgeon-general, Dr. Wyman was active in promoting reforms of far-reaching character. He was particularly interested in problems concerning the health of sailors in the merchant service, for the care of whom the Marine-Hospital Service was established. He made a special study of the physical conditions under which seamen are employed, and the result of his study is embodied in recommendations for legislation which Congress passed. He called special attention to the cruel treatment imposed upon deckhands on river steamboats in the West and investigated and exposed the barbarities inflicted on men employed in the Chesapeake Bay oyster fleets. In 1893 he succeeded in having a hospital for oystermen established in the Chesapeake Bay.

It was at the suggestion of Dr. Wyman that the first government sanatorium for the treatment of tuberculosis was established at Fort Stanton, N. M., and he was instrumental in securing the enactment of laws relating to quarantine, government regulation of the manufacture and sale of vaccine virus, antitoxin, and other therapeutic sera, and in the establishment of the hygienic laboratory in Washington.

Dr. Wyman was a member of the American Medical Association, of the American Public Health Association, and of many other medical societies. He was president of the American Public Health Association in 1902-3, of the Association of Military Surgeons in 1904-5, and of the American Medical Editors' Association at the time of his death, and had also held positions of honor and responsibility in many national and international gatherings.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent)

CASE OF PLAGUE IN EAST ANGLIA—SLIGHT STROKES—APPENDICITIS AND RHEUMATISM—EDUCATION MEDICAL OFFICERS' REPORT—INSURANCE BILL—MEDICAL DEPUTATIONS—OBITUARY.

London, November 3, 1911.

A case of plague has again occurred in Suffolk. The official announcement by the Local Government Board is sufficiently explicit as to this fact but reticent as to the source of infection. The case is that of a sailor admitted to the sick quarters of the naval barracks at Shotley (a few miles from Ipswich). This is where the first case in December, 1906, occurred and that, you may remember, was followed by several others during three or four weeks. In January, 1910, another outbreak occurred on the other side of the Orwell, just opposite Shotley. In September four cases, all fatal, occurred at Freston, about 6 miles from Shotley. Such is the so-called East Anglian epidemic, when, as reported to you at the time, rats, cats, and other furred animals, such as rabbits, hares, and ferrets, were found to be infected and a war of extirmination on them begun. The new case of a sailor was admitted on October 10 with symptoms of pneumonia. On examination plague bacilli were found and the patient was isolated, says the official statement "on the first discovery of suspicious symptoms," and, of course, all precautions taken to prevent the spread of the disease. The isolation has been strict since October 15, when the bacteriological diagnosis was complete. The attendants submitted to Haffkine's protective method. The period of incubation having passed without any contact being attacked we may consider the danger of further outbreak slight. The source of infection is uncertain, but it is stated in the locality that the sailor cut his finger when skinning a rabbit which was, perhaps, suffering from the disease. This may be so but cannot be proved for there is this serious hiatus in the evidence that there is no part of the rabbit preserved to submit to the bacteriologists. The M. O. H. for the district is satisfied that the County Council is acting with vigor and has been doing so ever since last year's cases. But the total extirmination of all vermin is hardly possible within a twelvemonth, but the campaign has been carried on continuously. In Ipswich 1,300 rats have been examined for the plague microorganism and in not one has it been found. It is intended to take still more strenuous measures to extirminate vermin in the small district invaded and to attempt to establish round it a rat-free cordon. All plans submitted to the council will be considered by the skilled staff.

"Slight strokes" were discussed in the Medical Section (R. S. M.) on October 24. Dr. Pruen introduced the subject in a paper in which he related a case of an old lady who was troubled with pins and needles in the right arm and leg, which came on suddenly and passed off in a few hours but not completely. A month later she had a stroke of the right leg. Within a year she had right hemiplegia, fatal in a few days. Dr. Pruen has since, by careful inquiries into the history of cases of obvious strokes, come to the conclusion that three-fourths of them have been preceded by symptoms like those in the case mentioned, or by giddiness, nausea, palpitation, faints, etc., either alone or combined, though mostly one symptom would predominate. These coming on suddenly in a patient over fifty, who had never had another attack, and disappearing gradually, he regarded as probably slight strokes, likely to be followed by one or two others and later by the well-known classical strokes. He looked to the vagus and sympathetic for explanation and considered degeneration of the vascular system with increase of tension as probable accompaniments. The changes in slight cases would naturally be slight and come on insidiously.

Dr. J. W. Carr regarded the paper as helpful in recognizing the danger that the symptoms might

indicate and the precautions as to future attacks. Dr. Parkes Weber thought the dulling of sensibility of the bladder seen in elderly persons was due to the muscular dullness rather than to the mucous membrane. Dr. Michael Foster mentioned cases of transient aphasia with partial paresis seen in pregnant women. Dr. Robert Hutchinson referred to transient hemiplegia sometimes seen in cases of migraine. He commended the paper as the experience of a general practitioner who had seen much of elderly patients.

Dr. Pruen in reply said he used the term slight strokes as a purely clinical one to cover various vascular conditions. He had considerable opportunities of watching old persons during life but was not permitted to make post-mortems. He therefore thought it well to make no attempt to deal with pathological conditions. He admitted having more than once made a mistaken diagnosis at first but he had always been able to correct the error as the case developed.

At the opening meeting of the Section of Pathology, on October 17, Drs. F. J. Poynton and Alexander Paine presented a further contribution to the study of rheumatism, being the experimental production of appendicitis by the intravenous inoculation of their *Diplococcus rheumaticas*. In their former researches these authors showed that their diplococcus, which they obtained from the effusion in joints in acute rheumatism, set up arthritis and cardiac disease if injected into rabbits. The infective agent in the new research was the diplococcus drawn from the fluid obtained by tapping the knee-joint of a boy of fourteen suffering from a first attack of rheumatic fever, brought to the hospital on the fifth day. They used for experiment in this series young rabbits six or seven weeks old and lay stress on this point. The first animal injected died from pericarditis. The second had a less dose. Multiple arthritis and mucous diarrhea followed and death after some days, from intussusception. A pure culture from this animal was used for the third—seven weeks old. Arthritis of the left knee developed with general illness, diarrhea, and death on third day. Post-mortem showed 1½ in. in middle of appendix acutely inflamed, early syovitis of knee, fatty areas of liver, excess of fluid in pericardium. The diplococcus was recovered in pure culture from the knee and the heart's blood. This rabbit was shown at the meeting with sections illustrating the inflamed mucous membrane of the appendix and the infective agent in the vessels of the mucosa and submucosa.

Other experiments confirming and extending the foregoing were detailed but results can only be stated in the space at my disposal. Appendicitis was found in early stage, later severe cases, ulceration, and further peritonitis from local deposits of the diplococcus injected into the veins. An interesting event was rapid destruction of the diplococci by the tissues which accounts for the difficulties of isolating the organism during life which have been reported. The mucous diarrhea seems a noteworthy symptom in connection with intussusception found in two cases. Concretions were not found. Indeed, the lesions began deep in the wall of the appendix. The middle part is the position in which stricture is often found in man and other results are evidently related to human appendicitis. In one case early peritonitis occurred with living diplococci in the effusion although there was no perforation. Altogether the results favor the common impression of some relationship between acute rheumatism and appendicitis. The authors do not claim priority over Adrian's results that in rabbits various micrococci produce appendicitis when injected into the veins and they give full credit to his masterly investigation which is quite in accord with their own. But he did not report ulcer formation, arthritis, or the state of the peritoneal fluid. He was occupied with the question whether appendicitis resulted from general blood infection or local injury.

The annual report of the medical officer of the Board of Education has been issued with the result of reviving interest in school hygiene and allied topics. General conclusions can hardly be drawn from the facts recorded in it, for to some extent it is a critical account of work in areas so various and in ways so different that comparisons are practically impossible. In a general way, however, it may be said that the findings of medical inspection in 1910 were similar to those of 1909. The report points out that the circumstances responsible for infantile mortality lead also to a high degree of sickness and disablement among children of school age and probably in a higher degree among adolescents and again among adults. Every step toward improving the health of children must, therefore, be a step toward diminishing disease and raising the standard of health of the general population. It is accordingly laid down that a State cannot effectually insure itself against disease unless it begins with its children, for many diseases and disabilities affecting adults spring directly out of those of earlier life. As examples the report says malnutrition, debility, dental caries, adenoids, and measles in childhood are the ancestry of tuberculosis in the adult—which may be taken as a type of preventable disease. The purpose of school baths (spray or douche) is not merely to cleanse dirty children but to train them in habits of cleanliness, so the board is ready to consider proposals from local authorities to install shower or any simple baths where there are difficulties for providing facilities for cleansing school children.

Yesterday Mr. Lloyd George received a deputation from the Irish Medical Association and the British Medical Association on points in his insurance bill, but the result is as uncertain as in former proceedings of this kind. The public are complaining that the Chancellor is superseding Parliament by his numerous conferences at the Treasury with the interested parties and comes down to the House to declare it is not necessary to debate this or that clause as he has amended it or settled it. If this is not accepted the guillotine soon falls. Among a number of new clauses he is bringing forward one establishes a "medical committee" to confer with the health committee. It can have no discussion in the House but, say many, it matters not, for he may alter it to-morrow. The British Medical Association does not admire the Chancellor's method but acting in the same way it cannot speak out. Just now it is also carrying on electioneering for the Medical Council in a manner more worthy of politicians than doctors.

Dr. Thomas H. S. Pullin, M. O. H. for Sidmouth and surgeon of the dispensary, has died at the age of eighty-seven. He was a Bart.'s man and took the double qualification in 1850; M.D., St. Andrew's, 1862, and the Fellowship of the Edinburgh College of Surgeons, 1882. He was through the cholera epidemic at Portsmouth in 1849 under a Board of Health and had filled many appointments.

I regret to report the death on November 1 of Dr. J. A. Coults, F. R. C. P., the very able physician of the East London Hospital for Children. He was a Cambridge graduate, had been Hunterian professor at the Royal College of Surgeons, wrote the articles on tuberculosis, infantile syphilis and rickets in *Allchin's Manual,* several others in the *Encyclopedia of Medicine,* the *Transactions of the International Medical Congress,* and was a liberal contributor to the societies and journals.

OUR CANADIAN LETTER.

(From Our Regular Correspondent.)

TYPHOID FEVER IN TORONTO—SALE OF DISEASED MEAT—OPENING OF THE MEDICAL SCHOOLS OF CANADA—FIRST ANNUAL CONGRESS OF THE CANADIAN PUBLIC HEALTH ASSOCIATION IN MONTREAL—OPENING OF THE NEW HOME OF THE TORONTO ACADEMY OF MEDICINE—DR. RACHEL R. TODD APPOINTED AS MEDICAL SCHOOL INSPECTOR IN TORONTO—THE WATER FILTRATION WORKS OF TORONTO.

MONTREAL, November 1, 1911

TYPHOID fever has been somewhat prevalent in Toronto and in some of its outskirts. In Swansea, which is, by the way, under the control of the Ontario Provincial Board of Health, there have been a large number of cases. It is said that conditions there are unsatisfactory from a sanitary point of view.

Dr. Chas. Hastings, the Medical Officer of Health of Toronto, like Dr. Wiley, although of course on a very much restricted scale, seems determined to preach the gospel of pure food and to continue to preach the gospel until definite results shall ensue. Dr. Hastings stated recently that there are approximately 500 head of cattle killed each week in the twenty private abattoirs of Toronto. The three veterinarians attached to the Board of Health are only able to make 116 post-mortem examinations per week. Of these 116 carcases examined, 13, on the average, are found to be diseased and 15 carcases or portion of carcases are condemned weekly. Dr. Hastings estimates that of the 500 beasts killed weekly in the private slaughter houses of Toronto 55 are placed on the market without any inspection whatever. According to the Medical Officer of Health, if all the work of examining cattle were concentrated in one large abattoir worked under a co-operative system, an efficient inspection could be made of every animal killed and no diseased carcases would be sold of cattle killed within the city limits.

Canada has been making rapid material progress during the past few years. She is regarded as almost the land of promise. It is pleasing to notice that with material progress, in most parts of Canada, educational progress has gone hand in hand. This applies to medical education. The Carnegie report found that in a population of seven millions or so there were two medical schools of quite the first rank, some others were fairly well conducted, and only a few came in for sharp criticism. As the medical schools of Canada have just reopened, it will not be out of place to briefly consider the status and conditions prevailing in the chief of them. Perhaps, mainly owing to the strictures passed in the report of the Carnegie Commission on the Halifax College, the college has been reconstituted as the medical faculty of Dalhousie University, its old home. Dalhousie College was founded in 1818 by the Earl of Dalhousie, whose idea was to establish a college on similar lines to Edinburgh University. In 1841 university powers were conferred upon the college and in 1868 a faculty of medicine was organized. Financial reasons caused the medical college to become detached from the university. Now the university has acquired the property and equipment of the college and will carry on its work. The staff has been strengthened and it seems safe to predict an era of prosperity for the medical faculty of the Dalhousie University.

The medical faculty of Toronto University has made greater strides than that of any university in Canada, and probably greater than that of any university of the world. This remarkable advance is chiefly due to the enlightened policy of the Ontario Government under Sir James Whitney. The government has let the university have money without stint to forward the cause of higher education, and the result is now shown in some of the most splendid university buildings, with the most modern equipment to be found anywhere and a highly trained staff of professors and lecturers. Of course, the medical faculty has shared in this progress; in fact, the medical department of Toronto University is easily its most important department and bids fair to take rank with the celebrated medical schools of the world. The medical faculty of the University of Toronto has made for itself a high standard. It is impossible to obtain a degree in medicine until five years have been spent in medical study. Furthermore, a goodly proportion of the students of medicine take a preliminary course of scientific study. Twenty per cent. of the students voluntarily enter the arts' course in natural science, fulfilling the requirements of the natural science course, which entitles them to a degree of Bachelor of Arts, that is, after the necessary examinations have been passed.

There is every prospect for a prosperous session of the faculty of medicine of McGill University. Applications for admission have been exceptionally numerous. This is owing to some extent to the fact that the magnificent building of the medical faculty, principally given by Lord Strathcona, was opened a short time ago by the late Governor-General. The building is now complete, the west wing of which will give accommodation to the department of hygiene and pharmacology and will be ready for the teaching of students. The department of hygiene in every medical school in these days bulks very large. Most authorities are agreed that preventive medicine is the medicine of the future, and it therefore behooves students of medicine to pay particular attention to this branch of medical study. Both as regards housing, personnel, and equipment the McGill medical faculty, hygiene department, is highly favored. The faculty has undergone some changes. Professor Alcock of St. Mary's Hospital, London, takes the chair of physiology; Dr. Wilkins has resigned the chair of medical jurisprudence, and the position has been taken by his assistant, Dr. D. D. MacTaggart. Dr. Armstrong becomes the senior in the department of surgery, rendered vacant by the death of Dr. James Bell.

It is expected by the authorities at Manitoba Medical College, Winnipeg, that there will be this session a larger number of students than ever before. Manitoba Medical College occupies a unique position in the great Northwest. This part of the Dominion is advancing by leaps and bounds, and it is anticipated that the West may ere long equal the East in population and in commercial and educa-

tional importance. Outside of Winnipeg the western provinces of Canada have not reached that stage of development when they can establish medical departments in their recently organized universities. Therefore, for some time to come, it will be the duty of Manitoba Medical College to provide medical educational facilities for the western part of Canada. According to the Canadian Medical Association journal of October, 1911, when Abraham Flexner visited Manitoba Medical College in May, 1909, he made two suggestions: That a full-time professor in anatomy should be appointed, and that a course in practical pharmacology should be established. Since then these suggestions have been carried out. E. J. Evatt, M.D., M.S., (Dur.), has been appointed professor of anatomy, and a course in practical pharmacology has also been established. So far as facilities for clinical instruction are concerned, Manitoba Medical College is indeed fortunate. The home of the college is situated in close proximity to Winnipeg General Hospital, and the staff of the latter and the faculty of the former are practically the same.

The medical faculty of the University of Laval, at Montreal, will have about the same number of students as usual—200 or so. The medical curriculum is five years. The university building is small and cramped, but the medical students have the use of the laboratories of the Catholic Universities of Montreal; Hôtel Dieu, 250 beds; Notre Dame, 140 beds; St. Paul, 100 beds, and in addition the Maternity and the Asile St. Jean Dieu for the study of obstetrics and nervous diseases..

The Western University Medical Department, London, Ont., has raised its standard. The Ontario Government, too, has decided to equip and maintain the Institute of Public Health and Preventive Medicine recently erected in proximity to the Victoria Hospital. This institution will be open to students of the medical school.

The first annual congress of the Canadian Public Health Association is to be held in Montreal November 21 to 23, 1911.

The formal opening of the new premises of the Toronto Academy of Medicine, 13 Queen's Park, Toronto, took place on October 26. The academy was formed five years ago by the amalgamation of four useful but separate bodies, the Toronto Medical Society, the Clinical Society, the Pathological Society, and the Ontario Medical Library Association. Of the 600 medical men of Toronto, 300 are members of the academy, and there are 50 outside members. The present home of the academy is beautifully situated in Queen's Park in a larger and better equipped house than the one formerly occupied. Dr. Helen MacMurchy's place on the medical staff of the Toronto schools has been filled by the appointment of Dr. Rachel R. Todd, as inspector.

Dr. Nasmith of the Toronto Board of Health has criticised adversely recently the principle of slow sand filtration. Referring to the work now going on in connection with Toronto's water supply, he said: "While the city has been occupying two years in building a filtration plant, the advance of science has declared the plant an antiquated piece of machinery." Dr. Nasmith, among other things, recommended the chlorinating of sewage and sterilizing the filtered water. In Europe it would seem that slow sand filtration of water has a fairly good record. Enteric fever has been practically abolished from London by the employment mainly of the method, and if the polluted water of the Thames can be rendered potable and comparatively free from hurtful germs, principally by slow sand filtration, then it would seem that similar methods applied to the water supply of Toronto should have, at least, equally satisfactory results. The problem of eradicating enteric fever, to all intents and purposes, has been solved successfully in the civilized countries of Europe; why then should not similar methods be employed generally with equal success on this contitnent. The situation cannot be so very different.

OUR BERLIN LETTER.

(From Our Regular Correspondent.)

SOCIETY OF NATURALISTS AND PHYSICIANS—SALVARSAN—EHRLICH'S ADDRESS—BACTERIAL CONTAMINATION THE CAUSE OF MISHAPS—RECENT EXPERIENCES OF OTHERS—WASSERMANN REACTION AS AN INDEX OF CURE—MERCURY IN CONJUNCTION WITH SALVARSAN.

BERLIN, October 15, 1911.

THE center of interest at the recent meeting in Carlesruhe of the Society of Naturalists and Physicians was Ehrlich's address on the subject of salvarsan. The numerous mishaps that had occurred in the course of the administration of salvarsan, stated Ehrlich, had been attributed to this drug itself. The vesical disturbances that had been reported from Prague had been the result of the decomposition of salvarsan from prolonged exposure to the air. Indurations and thromboses in the veins were the result of excessive alkalinity of the solutions. Fever, diarrhea, headache, and vomiting were attributed by Wechselmann to the bacteria contained in the distilled water. Jakimoff had shown that bacteria increased the toxicity of salvarsan; he had found that the addition of the colon bacillus to salvarsan increased the toxicity of the latter in mice. Under the influence of bacteria the cells of the body anchored more firmly the salvarsan, and less of this was left free to act upon the parasites. Cases in which disturbances in the cranial nerves, particularly in the auditory nerve, had been observed, following the use of salvarsan, were really cases of previous disease in these nerves, which under the influence of salvarsan responded by means of a reactive swelling, and if these nerves lay in narrow, bony canals the nerves were subject to injury in consequence of this swelling. That salvarsan was not alone in regard to this sequence was determined by Benarios, who gathered from the literature that there were 149 cases of neurorelapses after salvarsan and 122 after mercury. The cases of fatality following the use of salvarsan showed at autopsy encephalitis hemorrhagica. Patients with disease of the nervous system should be treated only by means of small repeated doses, and absolute rest and the avoidance of excesses should be enjoined. In the face of the large number of successful cases the number of unsuccessful ones was insignificant. The fundamental proposition that one might with one dose of salvarsan effect a complete cure had not been realized in human pathology, with the exception of recurrent fever and frambesia. In cases of tertian malaria in which quinine had failed salvarsan had succeeded. Bilharziosis had also responded favorably to salvarsan.

In the discussion which followed dermatologists and clinicians reported their recent experiences. Wechselmann of Berlin reported his results in 8,000 injections. In no instance had he noticed any case

of poisoning, although in the cases of very anemic young girls he had given four injections of 0.5 gram each in the course of three days. The frequent adverse by-effects were to be avoided by the use of absolutely freshly distilled water. Seven preparations that had been used with a stormy outcome by other physicians had been employed by him without causing any unfavorable reaction. Heart disease and nervous affections were not absolute contraindications to the use of salvarsan. The hemorrhagic encephalitis was caused by bacterial toxins and not by salvarsan.

Gennerich of Kiel recommended the use of purest distilled water. The Wassermann reaction after the injections of salvarsan behaved in the following manner: Abortive cases with a negative Wassermann showed, following the injection, a period of positive reaction whose duration was directly proportional to the remoteness of the initial lesion. In tertiary syphilis the injection of salvarsan changed a negative reaction into a positive one. Since latent cases were made positive, one possessed in the Wassermann reaction a means of determining whether a definite cure had taken place, particularly if after a year's pause in the treatment the reaction was negative. In abortive cases the speaker gave four injections of salvarsan at intervals of four days for the first three injections, and for the fourth after an interval of ten days, and in addition eight injections of calomel. In all other cases he gave five or six calomel injections and in addition five doses of salvarsan. By means of this combination of calomel and salvarsan a negative reaction could be attained in all cases. Also Meirowsky of Cologne believed that by means of three intravenous injections of salvarsan and simultaneous calomel administration syphilis could be cured. Weintraub of Wiesbaden said that he had treated many cases of cardiac and vascular syphilis by means of cautious doses of salvarsan with permanent or transient improvement. Cases of angina pectoris were completely cured.

There followed a series of speakers who extolled the virtues of salvarsan as a means of aborting syphilis. Some of them beheld in this drug, in conjunction with mercury, an absolutely certain remedy. Kromeyer, Isaac, and Schindler of Berlin took the common stand that the intravenous method was not available for all cases. To avoid mishaps the doses should be small. Kromeyer gave three times a week 0.2 gram, until a total of 5 grams was administered. Isaac injected salvarsan suspended in lard, while Schindler used as a suspension his preparation known as "Joha."

Ehrlich in closing the discussion stated that the abortive treatment was to be thought of only by the use of salvarsan; that in the later cases the addition of mercury was necessary; that neurorelapses were controllable by means of an intensive treatment, and that fatalities were rare and were then only the result of a faulty technique.

Progress of Medical Science.

Boston Medical and Surgical Journal.

November 9, 1911.

The Biological Basis of Specific Therapy. S. Flexner.
The Association of Mental Symptoms with Contusions of the Eye. E. R. Williams.
Vincent's Angina. E. H. Place.
Epithelioma. A Record Showing Common Factor of Irritation as a Cause. J. A. Honeij.
Case of Primary Sarcoma of the Middle Ear and Mastoid, Operation, Recovery. G. L. Tobey, Jr.

Biological Basis of Specific Therapy.—S. Flexner states that the parasite in some instances tends to withdraw into situations to which the curative agents gain access imperfectly and with difficulty. The lymph provides the essential safeguard against infection. The parasites possess the power of developing an effective resistance, called "fastness," to injurious chemical agents. The new qualities are the result of mutations among the parasites, which mutations are transmitted to successive generations of parasites, and are responsible for troublesome relapses, as in malaria, sleeping sickness, and spirochetal infection. The chronic carrier is to be regarded as a victim of this form of mutation among the microorganisms. The two properties that determine the availability of drugs in combating infection are a low degree of toxicity for the organs of the host and an absence of the tendency to produce "fast" strains of the parasite. The infections of the meninges illustrate the increased defenses of a microorganism by confinement in one locality. The success attained in the serum treatment of epidemic meningitis has suggested the availability of this method in other forms of meningitis. Experimental influenzal meningitis has been controlled by the use of an immune serum injected intraspinally. By means of a suitable combination of sodium oleate and antipneumococcus serum, experimental pneumococcus infections of the meninges can be controlled and abolished. The soap increases the vulnerability of the pneumococcus, but it must be prevented from uniting with the protein of the antiserum, which can be done by the addition of a minute quantity of boric acid. The effort has been made with some degree of success to control experimentally produced tuberculous pleurisy and meningitis by means of repeated injections of living leucocytes. The possible control of poliomyelitis by means of drugs is indicated by the fact that urotropin does exert some action when administered by the mouth. In this instance it furnishes a unique example of a chemical body being excreted into the cerebrospinal fluid. A number of derivatives of urotropin have been prepared, which exceed the latter in activity and which have been applied with some degree of success in the treatment of experimental poliomyelitis.

Mental Symptoms and Contusions of the Eye.—E. R. Williams points out that apparently trivial eye injuries often cause quite serious mental complications, and reports a series of cases illustrating this fact. The arrangement of von Merz, who first called attention to psychic shock to the eyeball, is somewhat modified by the author in the following classification: (1) Psychic shock causing temporary reduced vision without permanent damage to the retina. (2) Surgical or psychic shock causing serious retinal lesions with permanent decrease of vision. Traumatic delirium. In eye injuries there are symptoms closely resembling cerebral concussion and also surgical and psychic shock. The effect of air concussion in producing blindness was studied by von Merz during the Russo-Japanese War.

Vincent's Angina.—E. H. Place states that there can be no question that this disease is often confused with diphtheria, syphilis, stomatitis, and tonsillitis. From diphtheria it differs in being always an ulceromembranous process, which diphtheria is never primarily. Edema and marked and diffused redness may be absent in both, but their presence is entirely against uncomplicated Vincent's angina. In diphtheria it is uncommon to find a smear having the appearance of Vincent's angina. From primary syphilis the absence of infiltration and of any marked adenopathy and of other signs, and its rapid clearing with local treatment serve to differentiate Vincent's angina. From mucous patches, its more evident ulceration, its distribution, the absence of other signs, the smear, the absent Wassermann's reaction, are usually sufficient. From the other ulcerations of the mouth and throat Vincent's angina may be diagnosed by the smear and culture and the course and history. Ulceration very closely simulating Vincent's angina may be seen after the severer forms of

diphtheria and after serious streptococcus infections. The postoperative ulcerations of tonsillectomy, etc., may simulate the disease. The most satisfactory local treatment in the hands of the author has been the swabbing of the ulcer with hydrogen peroxide full strength or diluted one-half and then painting it with a 2 per cent. solution of chromic acid once daily.

Irritation as a Cause of Epithelioma.—J. A. Honeij notes that out of a group of 150 patients suffering from epithelioma 32 per cent. gave a positive history of irritation of some benign growth or injury to the normal epithelial surface.

Primary Sarcoma of the Middle Ear and Mastoid.—G. L. Tobey reports a case of this condition in a boy aged eleven years. Recovery followed operation and the use of Coley's serum.

Thyroparathyroid Secretion as Opsonin.—C. E. de M. Sajous believes that it is as an opsonin that the thyroparathyroid secretion produces its main effects, and recommends that thyroparathyroid preparations be used in various acute and chronic infections to enhance the opsonic power of the blood.

Fatalities of Delay in Rectal Diseases.—By J. P. Tuttle. (See MEDICAL RECORD, July 22, 1911, page 203.)

Sera and Vaccines.—J. H. Egbert and O. O'Neill review the mode of action and the indications for the use of the various sera and vaccines, and report cases illustrating the value of antistreptococcic serum, gonococcic vaccine, Coley's fluid, and pneumococcic vaccine.

Tuberculin.—C. Rayevsky believes that the true specific for tuberculosis is probably hidden in the tuberculins, and that of these tuberculinum purum is the one that comes nearest to the desired goal. Six cases are reported in which the use of this remedy produced good results.

Combined Vaccine Therapy in Pulmonary Tuberculosis.—G. Sanders states that the prostration, night-sweats, fever, and debilitating condition of a patient having pulmonary tuberculosis are considered to be due to a secondary infection, and by mitigating or removing the secondary infection, thereby increasing the vitality of the patient and also his resisting powers, one may accomplish a rapid cure of the tuberculosis. For this purpose the combined vaccines are injected. These consist of the following: streptococcus, multivalent, 50,000,000; staphylococcus, multivalent, 500,000,000; and colon bacillus, multivalent, 200,000,000 to each cubic centimeter vial. One half of this quantity is injected hypodermically. Used every other day, from four to ten injections seem to bring definite results.

Monthly Mortality.—H. A. Brown states that in 1909 a larger proportion of deaths occurred during the month of March than in any other month during that year, the percentages of total deaths for the year ranging from 9.56 in March to a low point of 7.41 in June.

Furunculosis as a Cause of Death.—L. I. Harris reports the case of a man aged twenty-two years, who succumbed to pyemia with sinus thrombosis and metastatic abscesses four days after coming under treatment for a furuncle on the back of the neck.

Symptomatic Parotiditis.—P. W. T. Moxom presents the history of a case of double parotiditis in a lady aged seventy years, occurring after an attack of appendicitis. The inflammatory process in one of the glands went on to suppuration. The other salivary glands were swollen but without pain or tenderness. After the evacuation of pus from the suppurating gland the patient made a complete recovery.

Phagocytic Power of Leucocytes.—L. Hektoen notes that the phagocytic power of the leucocytes may vary somewhat even in persons in health. At birth it is less than in the adult and decreases during the first months of life, the adult standard for streptococci, pneumococci, and staphylococci being reached about the third year of life. There is no conclusive evidence that the different kinds of neutrophiles differ in phagocytic activity. There are indications that their phagocytic power is below normal in myelogenous leucemia. The phagocytic power has been found above normal as regards pneumococci, streptococci, and staphylococci in pneumonia, scarlet fever, and other conditions where there are acute leucocytosis and a good prognosis. In pneumonia the leucocytes may be more resistant to heat than normal leucocytes; they may have greater attraction for pneumococci and take up more virulent germs than normal leucocytes. The destructive power of leucocytes in pneumonia and scarlatina for pneumococci and streptococci runs parallel with the phagocytic power. In severe cases of these diseases the phagocytic and destructive powers will be lower than normal. In recent exudates the leucocytes are more active as phagocytes for streptococci, pneumococci, and tubercle bacilli than the leucocytes of the corresponding blood. The exact causes of the increase in activity are not known, but it has been suggested that it is due to the predominance of young leucocytes. In certain chronic infections, notably pneumococcus endocarditis and chronic erysipelas, the phagocytic power of the leukocytes may be either above or below normal, and at times there may occur a distinct fall, which may be specifically limited to the infecting microorganism or observable only in the native serum, or both.

Mammary Adiposity.—By J. R. Guthrie and H. Albert. (See MEDICAL RECORD, July 1, 1911, page 50.)

Pathological Kinks of the Intestine.—By F. H. Martin. (See MEDICAL RECORD, July 8, 1911, page 103.)

Finger Phenomenon.—A. Gordon describes the following new diagnostic sign of organic hemiplegia: The forearm of the patient's affected limb is elevated and the elbow is placed on a table. The patient's wrist is then lightly embraced by the examiner's hand, with the thumb against the pisiform bone and the other fingers on the dorsal surface of the wrist. Pressure is then produced with the thumb against the pisiform body, and especially on its radial side. Care must be taken not to produce

pressure on the dorsal surface of the wrist where the extensor muscles are located. The fingers are then seen to extend and sometimes also to spread in a fan-like form. In some cases the extension is observed only in the last two fingers; in others all five fingers extend, and in still others the thumb and the next two fingers.

Sporadic Elephantiasis.—G. J. Winthrop reports a case of connective tissue hypertrophy with enlargement and induration of one leg, recurring in a woman aged 48 years. It would seem that the thrombophlebitis following labor produced chronic edema of the leg or by its extension caused an obliterative inflammation of the lymph-channels about the vein, with resulting lymph stasis.

Rebreathing in Anesthesia.—W. D. Gatch states that rebreathing, when properly regulated and when the oxygen supply is ample, is harmless and can be put to a valuable use. If one can prevent anoxemia, overconcentration of vapor, and too great a depth of anesthesia, one can obviate most of the serious objections to the closed method of giving ether. The process of rebreathing prevents the elimination of ether and chloroform by way of the lungs, and overventilation of the lungs hastens the elimination. It is suggested that after any administration of ether or chloroform overventilation of the lungs be brought about by the use of mixtures of oxygen and carbon dioxide. Morphine, or any other drug which depresses the respiration, retards the elimination of ether or chloroform.

Nitrous Oxide and Its Sequences.—W. H. Allen notes that nitrous oxide is the safest general anesthetic known. There is no direct effect on the heart and vasomotor systems, and the rise of arterial pressure is due to the light intercurrent asphyxia. There is no bad effect on the blood and the slight cyanosis due to the asphyxia can be disregarded. No changes in any of the body structures have been demonstrated. Nitrous oxide should be used in all cases in which chloroform and ether are contraindicated. Its own contraindications are those attending the asphyxia produced and in cases with narrowed or obstructed air passages, serious cardiac disease, extreme youth, and advanced arteriosclerosis. Its advantages are its safety and rapidity, and the comfort of the patient. The disadvantages are the narrow zone of application with consequent uncertainty of muscular relaxation, the need of skill in administration, and the expense. Special apparatus is required. For routine use the author employs the nitrous oxide and oxygen-ether sequence.

Diseases of the Prostate.—L. B. Wilson and B. F. McGrath present the results of a study of 468 cases of which seven were tuberculous. The ordinary picture of acute prostatitis in the text-books is misleading, as it gives the symptoms of the severe parenchymatous form, whereas both the lighter forms, the catarrhal and the follicular, are much more frequent. Gonorrhea is the most common cause of all the forms. The greater part of the bladder troubles of old people are due more to exacerbations of chronic prostatitis than to hypertrophy. Atrophy of the organ has multiple and quite different causes. It is doubtful whether true atrophy ever results after castration in existing hypertrophy, though it can occur after operations. Associated with exhausting diseases it is found in connection with atrophy of all the body structures. Stricture is a common cause of mechanical atrophy of the organ, caused by the pressure of the stagnating urine. Senile atrophy is to be considered as prostatic atrophy in the narrower sense, since it can occur in advanced age without any cause as yet determined. The prostate may become apparently completely destroyed in suppurative conditions from gonorrhea, tuberculosis, etc. Concretions may set up no symptoms or may cause chronic inflammation and suppuration.

Hyperidrosis Universalis.—H. Herbert reports a case of this condition associated with continuous fever in a man aged twenty-two years.

Improvement in Therapeutics.—B. Reed states that this can be obtained only by raising the standard of the doctorate to a higher plane. Improvement calls for more thorough study of functions in both health and disease and a still more intimate acquaintance with the more reliable remedies.

Carcinoma of Clitoris.—By C. D. Lockwood. See MEDICAL RECORD, July 1, 1911, page 50.)

Isolation of Typhoid Bacillus.—D. M. Lewis reports a case of typhoid fever traced to drinking from a well that had been contaminated by laborers.

Rejuvenation of Cultures of Tissues.—A. Carrel states that the rejuvenation consists in removing from the culture substances that inhibit growth and in giving to the tissue a new medium of development. It is accomplished by extirpating with a cataract knife the fragment of coagulated plasma containing the original piece of tissue and the surrounding new cells, which are washed for several minutes in normal or slightly hypotonic Ringer's solution. This rejuvenation shows that, under the conditions and within the limits of the experiments, senility and death are not a necessary, but merely a contingent, phenomenon.

Infectivity of Secretions and Scales of Measles.—J. F. Anderson and J. Goldberger find that the nasal and buccal secretions of uncomplicated cases of measles may be at times but are not always infective for the monkey. It is highly probable that the desquamating epithelium of measles in itself does not carry the virus of the disease.

Phenol Gangrene.—E. J. Brown reports a case of this condition in a boy aged five years, caused by the application of a phenol ointment of unknown strength to a bruised finger end.

Sodium Perborate as a Surgical Dressing.—A. Herzfeld states that he has used sodium perborate successfully, not only in epistaxis, but also in secondary hemorrhage after adenoid operations and tonsillotomies. He has also used it frequently in infected wounds, in acute and chronic ulcers, and in three cases of diabetic gangrene, in which the results were marked.

Ureteral Catheter Coupler.—B. Harris has devised a conical needle by means of which a syringe may be attached to a ureteral catheter.

Acute Iritis.—N. Bishop Harman, in discussing this subject, contrasts the signs of iritis, glaucoma, and conjunctivitis. The most important of these is the character of the pupil. It is normal in acute conjunctivitis, small and sluggish in acute iritis, wide and paralytic in acute glaucoma. In iritis the altered color of the iris is striking. Discharge is characteristic of conjunctivitis; it is absent in iritis and glaucoma.

Treatment of Diabetes Mellitus.—E. I. Spriggs, in continuing his article on this subject, devotes attention to the treatment of cases with diaceturia.

Sarcoma of the Thymus.—W. Sheen, C. A. Griffiths, and H. A. Schölberg report two cases of this rare con-

dition. In the first case the bilobate character of the growth as revealed at operation, coupled with microscopic examination of some of the pieces of growth then removed, allowed a probable diagnosis of sarcoma of the thymus to be made during life. Both cases were in young males and showed an acute onset; dyspnea, at first in attacks, dilated veins of the neck and thorax, swelling of the lower part of the neck, and dulness over the manubrium. Direct laryngoscopic examination was of value in determining the site of the obstruction. Division of the manubrium sterni and the removal of portions of the growth pressing on the trachea permanently relieved dyspnea. The clinical conditions unfortunately seem to show that there is little hope of ever getting a case so early that the growth can be entirely removed.

Operative Treatment of Badly United Fractures.—W. Arburthnot Lane believes that no operation in surgery may make a greater demand on the skill, resources, and ingenuity of the surgeon than that requisite to restore a badly united, useless bone to its normal form and functions. The chief obstacle in many cases is the difficulty in approximating the edges of the skin incision and in retaining them in accurate apposition. Surgeons are learning by painful experience that they cannot fix fragments in fractures by foreign bodies with the asepsis attained in abdominal and other operations.

Venesection.—R. Fortescue Fox states that this ancient method of treatment, which so suddenly disappeared from medical practice, has been again employed in a guarded manner and with good results in a variety of cases. The chief indication for venesection is cyanosis with distention of the right heart. To this is attributed its beneficial action in mitral disease and in some cases of bronchitis and pneumonia. No mere mechanical relief to the heart can, however, explain the observed effects. Venesection in some cases appears to influence in a favorable manner the progress of specific disease, both acute and chronic, probably by heightening the natural resistance of the tissues; it helps to restore the balance of the circulation and the normal distribution of the blood by a dilator effect on the arterial system; a small venesection may have a powerful and apparently disproportionate influence, not only in quieting the circulation, but the nerve centers also. This is witnessed in uremic coma or convulsions and in the crises of pain and dyspnea in aneurysm. Excessive blood pressures have been more or less permanently reduced by venesections far too small to produce such effects in a direct manner. Such facts as these suggest that the respiratory and vasomotor centers are concerned in these actions: and that there are, in truth, morbid states of the circulation and the nervous system, both acute and chronic, which are in some unknown manner peculiarly sensitive to a slight reduction in the amount of the circulating blood.

Prevention of Anthrax Infection.—C. W. Ponder states that civilized governments should forbid the importation of hides or skins unless either these have been submitted to the ordinary "wet-salting" process immediately after flaying; or if cured by drying they have been converted back to the "wet-salted" state by the "formic-mercury" process before leaving the country of export. If such regulations were adhered to one would hear no more of anthrax among the dock laborers and warehousemen, nor of those sporadic cases which are continually cropping up in the tanneries in different parts of the country.

Treatment of Plague.—V. B. Nesfield notes that early incision into a plague gland produces an immediate improvement in the patient's condition. The temperature is lowered and the severe headache alleviated, and if the patient is seen during the first 24 hours the probability of his recovery is very great.

Acetonuria in Childhood.—R. S. Frew concludes that acetonuria occurs in childhood with great frequency. In the large majority of cases the carbohydrate starvation necessary for its production is caused by a temporary failure of digestion. This loss of digestive power can be brought about by mere change of diet. It is more easily set up the younger the child, and the digestive instability becomes less marked as age advances. About three days are required before the digestive processes can accommodate themselves to a change of diet. Disease, with few exceptions, has no influence on the production of acetonuria in childhood.

Causation of Beriberi.—E. A. Cooper and C. Funk find that the polyneuritis induced in birds by a diet of decorticated and polished rice is not due to the deficiency of phosphorus compounds, but to the absence of some substance not of protein nature, devoid of phosphorus, soluble in water and acidulated alcohol, dialysable, and precipitated by phosphotungstic acid. The precise nature of this substance is being investigated.

Carbolic Acid Coefficient of Disinfectants.—F. T. Marchant states that the Rideal-Walker method of determining the carbolic acid coefficient of a disinfectant often furnishes results which are discrepant—a subculture tube often shows a growth when another tube, containing the same culture exposed to the same dilution of a disinfectant and for a shorter period of time, fails to do so.

Leishmania and Mosquitos.—G. Franchini believes that the *Leishmania donovani* can live and develop in the digestive tube of the anopheles.

Drill and Development.—L. B. Cane believes that even a few months' military training is responsible for definite and well-marked progress in physical development. Not only this, but the enforced discipline and regular habits cannot fail to be of benefit and to prove of distinct value in after life.

British Medical Journal.

November 4, 1911.

The Surgical Requirements of Narcosis and the Available Methods. D. W. Buxton.
Preliminary Note on Experimental Investigations on the Pituitary Body. Dr. Handelsmann and Sir Victor Horsley.
Acute Poliomyelitis; With Special Reference to the Outbreak in Plymouth, Stonehouse, and Devonport. A. B. Soltau.
Clinical Observations on an Epidemic of Acute Poliomyelitis in Cornwall. A. Gregor and L. B. Hopper.
Epidemic Anterior Poliomyelitis in Huntingdonshire. C. B. Moss-Blundell.

Methods of Anesthesia.—D. W. Buxton states that the safest method of employing ether is to inject 1/100 gr. atropine, or this together with morphine and scopolamine, half an hour before giving ether by the open method.

Pituitary Body.—Dr. Handelsmann and Sir Victor Horsley state that their experiments do not confirm the conclusion reached by Cushing and others that the anterior lobe is the essential element of the gland.

Poliomyelitis.—A. B. Soltau reports an epidemic of this disease which has occurred this year in the towns of Plymouth, Stonehouse, and Devonport. The author has been able to collect 73 cases. In discussing the mode of transmission, he believes that air or dust conveyance is the most probable one. It seems that the heat and dust of 1911 have been factors in maintaining the virus at a high rate of potency and in favoring its dissemination.

Poliomyelitis.—A. Gregor and L. B. Hopper describe the disease as it presented itself during a recent epidemic in Cornwall. One of the interesting points noted was that during this epidemic there were also a great many cases of herpes zoster. The possibility is suggested that there may be at work the same organism in both diseases.

Poliomyelitis.—C. B. Moss-Blundell reports a series of 15 cases of this disease which recently prevailed in Huntingdonshire. Three of the cases occurred in one family. The author notes that there did not seem to be any association between the sanitary condition of the houses and the disease. The weather at the commencement of the outbreak was very hot.

Insurance Medicine.

Some Suggestions Regarding the Means of Detecting Adverse Selection.—By Arthur B. Wood. (See page 1063.)

Prognosis in Examinations for Insurance.—Th. Eschenburg, in communicating his experiences as a medical director, says that he has often been surprised at the lack of agreement between the anamnestic and physical findings of the medical examiners and the prognosis expressed by them in cases of applicants for insurance. It seems that the practice of medicine gives better training in diagnosis and treatment of disease than in making conclusions as to the future health of the patient and the duration of life he may expect. As a rule, the prognosis of the medical examiner is too optimistic. Thus one examiner recommends the acceptance of an applicant whose father died of tuberculosis and who himself has suffered from tuberculous inflammation of the lungs, in the course of which tubercle bacilli were found in the sputum. His sole ground for the good prognosis was the belief that the tuberculous focus has become "encapsulated." Another sees nothing objectionable in a patient whose family history suggested tuberculosis and who himself has suffered from repeated attacks of pleurisy, involving the diaphragmatic pleura especially. Still another gives a reassuring prognosis for an applicant, because of his muscular development and abundant subcutaneous layer of fat, though very suspicious apical signs are present and the history of a stay in a sanatorium for pulmonary diseases is mentioned. Another class of cases concerns applicants with disease of the heart valves. While compensated valve lesions are *per se* not necessarily indications for declining an applicant for insurance, yet many an applicant suffering from a valvular lesion has been recommended in spite of a history of repeated rheumatic attacks.

Occasionally the examiner's prognosis is too pessimistic. Thus, a youthful applicant is not recommended for insurance because of an irregular heart action, although no other pathological findings are present.

Frequently, too optimistic prognoses are given in cases of luetics, where the possibility of the development of parasyphiltic nervous lesions should certainly enjoin caution. Too often symptoms of beginning tabes or paresis are explained by the word "neurasthenia"! The rôle of alcohol is also frequently underestimated, many applicants being recommended for insurance though strong probability of confirmed alcoholism is suggested by the history and physical findings. Another pathological condition that is underestimated is otitis media; in one such case an applicant was recommended for life insurance, although two years' treatment of the existing inflammation of the ear failed to cure the affection.—*Blätter für Vertrauensärzte der Lebensversicherung,* January and February, 1911.

Insurance During Pregnancy.—Tissier thinks that insurance of a pregnant woman should be postponed until the termination of pregnancy. There can be no reason for haste in the matter on the part of the insurance company, for an insurance policy is a contract made for a long term of years, while a few months decide the course of pregnancy. Of course, pregnancy introduces certain well-marked difficulties in prognosis. Moreover, the physical examination of a pregnant woman is never very satisfactory, as many temporary changes take place in the organs. The applicant, too, is better served, if termination of pregnancy is awaited, because many functional disorders occurring at that period imitate acute organic or chronic functional disease. In case all these objections do not outweigh some other reasons for insuring a given pregnant woman, in case of primiparæ, at least, such reasons should not be allowed to outweigh the risks taken. In the case of multiparæ, a careful history of preceding pregnancies should be obtained. Any cause for which one may hesitate to recommend a nonpregnant woman for insurance should in case of pregnancy be looked upon as a reason for nonadmission for insurance.—*Proceedings of the Third International Congress of Insurance Physicians.*

The Alcohol Problem in Medical Examinations.—T. D. Crothers says that all life insurance companies are becoming painfully conscious of the influence of alcohol in the risks that they constantly assume. There is great confusion in their theory and practice, some taking a very decided stand against insuring alcoholics of any type, others insuring "moderate" drinkers, still others laying stress upon the kind of alcoholic beverage the applicant habitually uses. Frequently, the policy of the company depends upon the existence of moderate drinkers among its officers and medical examiners. Crothers cites an illustrative case of an applicant who was reinsured for a large sum, though Crothers advised against it because of the admitted "moderate drinking" of the applicant. The latter died one year later of pneumonia. Pneumonia seems to be a special disease following the use of spirits. Cerebral hemorrhage, palsies, and arterial hypertension are other conditions favored by the use of alcohol. Many applicants deny the use of alcohol yet show unmistakable signs of alcoholism. It must be remembered, too, that constant "moderate" drinking is more dangerous for the health than occasional excesses. Alcohol increases susceptibility to disease and mortality among diseased persons. Frequently a psychological and physiological study of the applicant, of his habits, surroundings, etc., gives more clues to the effects of alcohol upon him than any discoverable lesion of the heart or kidneys. Mental conditions produced by alcohol, vasomotor instability marked by flushes, venous congestion, etc., are valuable indicators of the injury done, and are more significant than albumin in the urine or a high pulse beat. The man whose highest pleasure in life is gratification of his bodily wants, passions, and impulses, is also inviting early death and disease. Alcohol is his frequent aid.

The examiner should also be on the lookout for persons who are reckless of their health, abuse it in every way, and expect nature to repair it. Even if such men pass the usual physical standards of insurance companies, they are very bad risks because of their life habits. The medical examiner must also determine whether the use of alcohol may not be symptomatic of other abnormal conditions, for instance, drug-taking, etc. The examination blanks provided by insurance companies are very minute, yet frequently quite inadequate for "sizing up" an applicant. Many applicants should be studied continuously for a long period and medical examiners should be paid expert fees for such work. Insurance companies should employ expert physicians for this work, just as railroads employ experts for the study and prevention of accidents. There is something farcical in expecting the medical examiner to give a clear account of a man, insuring for a large sum, for a five- or a ten-dollar fee, while the agent gets several hundred dollars. The five-dollar fee cannot pay for the time that ought to be spent in studying an applicant for a large policy, and the insurance company gets what it pays for, indeed, but not what is important in sizing up the risk.—*Lancet-Clinic,* November 4, 1911.

Blood Pressure in Insurance.—J. S. Lankford says that in order that blood-pressure results may prove useful uniform standards of measuring should be adopted. The sleeve or cuff should be at least 5½ inches wide; the test should be made in a recumbent position on the level of the heart; the left arm just above the elbow should be used. The limits of normal variation in blood pressure are pretty wide, but the following figures may be used as standards: young children, 85 to 100; older children, 100 to 110; young

adult females, 110 to 120; young adult males, 115 to 125; older ages, up to 145 or 160. From the insurance standpoint, the low pressure in tuberculosis is a most important fact; in many cases it is an early diagnostic symptom of the disease. In all diseases leading toward great exhaustion the pressure is lowered, unless there is a toxemia of some kind or some organic disease of the heart or kidneys.

The all-important thing about pressure readings in insurance is that the sphygmomanometer reveals the earliest indication of heart and kidney lesions, even before a murmur can be heard or a trace of albumin found. In fact, it will show toxic blood conditions that lead on to heart and kidney diseases long before any other evidence of abnormality can be discovered. In sixty-four tests in various heart lesions, Lankford found the pressure above normal in all but five, and these were in the terminal stage where dilatation and exhaustion caused low pressure. Of thirty-seven cases of acute and chronic nephritis all showed high pressure, varying from 165 to 250. A very important stage of high pressure precedes the development of manifest heart or kidney diseases, and may be caused by the present-day nerve strain, impairing digestion and leading to the formation of various toxins and to autointoxication. Lankford predicts that testing blood pressure will become a universal requirement within certain limitations in life-insurance work. He is certain that no progressive physician can afford to be without a sphygmomanometer in the diagnosis and treatment of disease.—*Texas State Journal of Medicine*, November, 1911.

Chronic Affections of the Veins.—Moritz says that behavior of the venous system gives many important indications in insurance examinations. General venous engorgement may be due to chronic bronchitis with emphysema, to valvular disease of the heart, or to insufficiency of the myocardium. Frequently persons suffering from venous congestion impress the layman as healthy and "full-blooded." Local venous engorgement is usually due to mechanical causes. A most important instance of this is found in hemorrhoids, and from the insurance standpoint may be essential and independent, or symptomatic of abdominal conditions. The former accompany constipation and are frequently seen in persons of sedentary habits; the latter are most important evidence of organic disease, and sufferers from them must be looked upon as hazardous or substandard risks. Essential hemorrhoids must be judged in each individual case, and such complications as hemorrhage, spasm of the sphincters, periproctitis, fistulæ, fissures, ulcerations, etc., carefully looked for. In general essential hemorrhoids should not bar admission to insurance, but such admission may be delayed until complications have been cured or operative removal of the hemorrhoids themselves effected.

The next important type of venous engorgement is found in varices of the legs, with the accompanying chronic skin affections and ulceration. Here, too, the division into essential and symptomatic varices is very useful. The latter must be judged by the nature of the causative illness, which will determine the prognosis and the advisability of recommending an applicant for insurance. The former must be judged with reference to the age of the patient, the severity of complications, the probability of cure, etc. The last type of venous engorgement is exemplified in varicocele, and the gravity of this affection has been greatly exaggerated. It is more important as a frequent indication of abnormal sexual life than as an independent lesion, for symptoms referred to it are more probably caused by some sexual anomalies.—*Proceedings of the Third International Congress of Insurance Physicians.*

Asthma and Insurance.—Mahillon of Brussels, Belgium, holds the following views in regard to the admission of asthmatics for insurance: Young subjects, that is, persons below 35-40 years, whose antecedents are free from tuberculosis, who are not specially exposed to tuberculous infection, in whom asthmatic attacks occur at long intervals only and do not last more than 24 to 48 hours, who do not cough, do not raise sputum, suffer from no dyspnea, and whose hearts are not hypertrophied or dilated, should be recommended for life insurance at the ordinary premium but for a limited number of years. Asthmatics over 45 years of age, especially stout subjects, in whom deposition of fat about the heart may be suspected, and who are gouty, arteriosclerotic, or emphysematous, are not admissible. They belong to the class of people whose life is in no immediate danger, who may even attain advanced age, but in whom no prognostic estimate of any value can be made. Of course, such persons are not to be excluded from insurance at a more or less advanced premium, and under various other conditions protecting insurance companies.—*Proceedings of the Third International Congress of Insurance Physicians.*

Miner's Nystagmus.—Hessberg details the case of a man who developed marked nystagmus during his occupation as miner and put in a claim for indemnity. The legal aspect of the matter, as presented by Hessberg, is applicable only in Germany, but the medical interest of the case is a wider one. It appears that nystagmus is a frequent occupation disease among German miners, developing among such as are compelled to work in a half-erect position with eyes directed upward to the "ceiling" of the mine, upon which they are working. A contributory cause is found in the poor illumination of mines. The real cause, however, is not yet quite clear, for nystagmus develops only in a small number of workers. According to the most accepted opinion, this nystagmus is a neuropathic affection, only secondarily affecting the eye muscles by lowering their normal tone. Miners having weak eyes are more susceptible, especially as compensating eyeglasses cannot be very well worn during mining work. In addition any illness or habit, such as alcoholism, producing a weakened state of the body, seems to predispose to this affection. Frequently this type of nystagmus appears to be inconstant, being evident only when the miner is at work in the mine.—*Zeitschrift für Versicherungsmedizin*, October, 1911.

Increased Duration of Life in France.—Lannelongue points out the fact that the average length of human life in France has increased by 20 per cent. in the last 25 years. At the beginning of the last century the average duration barely exceeded the age of 30, in 1880 it was up to 40, and now it varies between 47 and 48. The progress of science, which has lowered the rate of mortality from epidemics and contagious diseases, and the development of hygienic principles among all closses of society have helped to delay the inevitable hour. But there is unfortunately another reason which is not so satisfactory. It is the steady diminution of the birth rate. Up to the age of 2 years infant mortality is very high. But of 1,000 infants from 200 to 300 die in the first years of childhood, and this mortality naturally has the result of considerably diminishing the average rate of life. Now as the birth rate has been decreasing for some time, fewer infants die, and the average rate of human longevity will further increase in proportion to the further decline of the birth rate.

Workmen's Compensation.—A brief has been prepared for presentation by the National Civic Federation to Congress in support of the Federation's Workmen's Compensation bill. The brief gives a rough classification of the different forms of compensation law. The arbitrary form gives the injured workman a right to compensation in every case and to the exclusion of all other remedies. This is the common form of "compulsory insurance." The simple form, compulsory compensation, gives the injured workman the right to compensation in every case except when the injury is caused by his own serious misconduct. The supplemental form adds to the liabilities of employers, and the elective form permits masters and servants to contract with each other in case of injury.

Book Reviews.

Criminal Psychology. A Manual for Judges, Practitioners, and Students. By Hans Gross, J.U.D., Professor of Criminal Law at the University of Graz, Austria; formerly Magistrate of the Criminal Court at Czernovitz, Austria. Translated from the Fourth German Edition by Horace M. Kallen, Ph.D., Assistant and Lecturer in Philosophy in Harvard University. With an Introduction by Joseph Jastrow, Ph.D., Professor of Psychology in the University of Wisconsin. Boston: Little, Brown & Co., 1911.

Rarely is a book written as this has been, by one who is able to combine the erudition of the scholar with the practical wisdom of the man of affairs. The presiding magistrate and the professor of criminal law are both represented in the author of this book, which has already achieved the distinction of a classic. Criminal psychology is not what this title would at first indicate, namely, the psychology of the criminal, but is of broader scope; it takes up the psychology of everything pertaining to the administration of justice. The psychology of the judge, the psychology of the witness, the psychology of the prisoner are all included. The book is divided into two parts. The first deals with the subjective conditions of evidence, or the mental activities of the judge. The second part deals with the objective conditions of criminal investigation or the mental activity of the examinee. In the first part are included the following topics: method; psychological lessons, such as integrity of witnesses, correctness of testimony, egoism, secrets, etc.; phenomenology or the outward expression of mental states, including the various signs of character, reflex movements, dress, physiognomy, and the hand; and the making of inferences, including a discussion of proof, causation, analogy, probability, chance, inference and judgment, mistaken inferences, etc. The second part of the work takes up in detail the subjects of sense perception, perception, imagination, intellectual processes, the association of ideas, memory, the will, emotion, etc. It also discusses the conditions of giving testimony; the differences inherent in women, in children, and senility; and the influences of habit, heredity, superstition, etc. The important topic of mistakes is considered from the viewpoint of illusions, hallucinations, and the actual lie. This is a mere and incomplete skeleton outline of the plan of the book. Every one of its 500 pages is replete with interest not only to the general reader and to the lawyer but also to the physician, whose knowledge of the human organism enables him to penetrate deeper than others into the innermost sources of human action. The style of the author scintillates with wit, and in its wealth of allusions indicates the breadth of his culture. The translator has succeeded in presenting the meaning of the writer in idiomatic and elegant English.

Zabludowski's Technik der Massage. Dritte, veränderte, und vermehrte Auflage bearbeitet von Dr. J. Eiger, Leitender Arzt des Berliner Ambulatorium für Massage. Mit 80 Abbildungen. Leipzig: Verlag von Georg Thieme, 1911.

Zabludowski spent twenty years of his his life in Berlin, occupied in teaching and practising medical massage, and his book on the subject has attained a well deserved popularity in Germany. The present third edition contains exact descriptions of the various procedures employed in massage, names the indications for them, and gives numerous therapeutic hints regarding the preparation of the room and the patient for massage, the frequency for treatments, the employment of mechanical devices, etc., etc. The theory of massage is touched upon only as far as it throws light upon the art of the procedures. The volume is a valuable text-book on the subject it considers. Illustrations are frequent and make many directions very objective and easily understood by the reader.

Practical Pathology. A Manual of Autopsy and Laboratory Technique for Students and Physicians. By Aldred Scott Warthin, Ph.D., M.D., Professor of Pathology and Director of the Pathological Laboratories in the University of Michigan, Ann Arbor. Second Edition, Rewritten and Enlarged. Ann Arbor: George Wahr, Publisher, 1911.

The second edition of this useful book appears practically as a new work, for it has been largely rewritten and more than doubled in size. As is customary, the text is divided into two parts, of which the first is concerned with the methods of performing post-mortem examinations and with the study of the gross material, while the second is devoted to the technique of the preservation of tissues and the procedures necessary for their microscopic examination. The book is characterized throughout by a strongly individual note which adds greatly to its interest and value, for it incorporates the results of the author's very extensive experience as a practical pathologist and as a teacher, and consequently abounds in original suggestions and methods. Like most workers in this field the author is abandoning celloidin imbedding more and more in favor of the paraffin method, which has now been improved to such an extent that it almost equals the other in simplicity and expedition, while it is its superior in nearly all other respects. A wise discrimination has been shown in the chapters on preservation, staining, etc., which include a sufficient variety of formulæ for all practical purposes and adequate discussions of their respective advantages, while all useless lumber has been omitted. The work may be commended as a thoroughly modern and satisfactory guide for the autopsy room and laboratory.

Compendium of Regional Diagnosis in Affections of the Brain and Spinal Cord. A Concise Introduction to the Principles of Clinical Localization in Diseases and Injuries of the Central Nervous System. By Robert Bing, Privat-Docent for Neurology in the University of Basle. Translated by F. S. Arnold, B.A., M.B., B.Ch. (Oxon.). Revised by David I. Wolfstein. With 70 Illustrations. Price, $2.50. New York: Rebman Company, 1911.

This little book purports to be an easily and quickly consulted work of reference, accurate and comprehensive, and yet clear and simple—a practical vade-mecum of a didactic character. The author states that only such material has been put forward, in the main, as seems firmly established, and the discussion of theories and controverted points is avoided. Regional diagnosis of brain and cord affections implies, of course, a knowledge of the anatomy and physiology of the nervous system. It is based on symptoms and signs arising from injury or destruction or impairment of function of separate structures of the nerve centers. These structures, broadly speaking, comprise only nuclei and tracts which have definite locations and definite functions. These locations and functions are now pretty well known and understood, and regional diagnosis has, therefore, assumed of late years a very practical importance for surgical as well as medical purposes. In the plan of the book, transverse or systemic diagnosis of lesions of the spinal cord is first taken up; the tracts, cell groupings, and mechanisms are described, and the localizing value of motor and sensory disturbances considered. This is followed by a consideration of the longitudinal or segmental diagnosis of cord lesions. The second division of the work is devoted to the regional diagnosis of brain lesions. A knowledge of the morphology of the brain-stem is assumed. The topographical anatomy is, however, described. General rules for localization are laid down. Special reference is made to the differential diagnosis of central and peripheral affections in the semeiology of the nerves of the brain-stem. Lesions of the cerebellum are covered in only fourteen pages. In the section on lesions of the cerebrum, the basal ganglia, and the hypophysis there is an anatomicophysiological introductry chapter, followed by chapters on the localizing value of motor and sensory disturbances of cerebral origin, on visual and on speech disturbances, and on certain rarer cerebral symptoms. The special chapter on the localizing value of disorders of speech is rather short, comprising but three pages. The illustrations in the book are mainly diagrams employed by the writer in lectures. The book will scarcely take the place of a text-book, but will be helpful for ready reference, especially for those who have considerable knowledge of the subject.

A Manual of the Practice of Medicine. Prepared especially for Students. By A. A. Stevens, A.M., M.D. Professor of Therapeutics and Clinical Medicine in the Woman's Medical College of Pennsylvania; Lecturer on Medicine in the University of Pennsylvania; Physician to the Episcopal Hospital and to St. Agnes Hospital; Assistant Physician to the Philadelphia Hospital; Fellow of the College of Physicians of Philadelphia, etc. Ninth Edition, Revised. Illustrated. Price, $2.50. Philadelphia and London: W. B. Saunders Company, 1911.

In addition to being revised, this new edition contains articles on acute dilatation of the stomach, mucous colitis, sprue, suppurative cholangitis, beriberi, Malta fever, sleeping sickness, plague, and pellagra. The book still retains its elementary character, and is of the same size as before.

Society Reports.

MISSISSIPPI VALLEY MEDICAL ASSOCIATION.

Thirty-Seventh Annual Meeting, Held at Nashville, Tenn., October 17, 18, and 19, 1911.

(*Continued from page 1049.*)

THE PRESIDENT, DR. ROBERT H. BABCOCK, CHICAGO, IN THE CHAIR.

Frequency and Etiology of Cholecystitis.—Dr. CHARLES N. SMITH of Toledo, Ohio, drew the following conclusions: 1. That in the case of cholecystitis two conditions existing simultaneously were necessary, namely, first, obstruction of the biliary current, and, second, bacterial invasion. 2. The mechanical irritation and the trauma produced by gallstones were a predisposing factor in cholecystitis, second only in importance to obstruction of the biliary flow. 3. The pathway of infection commonly was through the portal vein, occasionally through the doudenum and common ducts, rarely through the hepatic duct artery, and then, owing to the bacteriemia attending a general infectious process, and most frequently indeed through the lymphatic circulation.

Symptomatology and Diagnosis of Cholecystitis.—Dr. BAYARD HOLMES of Chicago confined his remarks to the symptoms of toxic, noninfectious cholecystitis, and said that the study of the symptoms of the toxic, noninfectious cholecystitis was based upon a meager material of forty-six cases, of which thirty-two were operated on by himself for drainage o fthe gall-bladder. Seven of these forty-six cases were operated upon after a diagnosis was made by other surgeons. He spoke of the objective symptoms and findings. In every one of the thirty-two cases operated on Riedel's lobe had been distinctly palpated and diagnosed by auscultatory percussion and the diagnosis confirmed at the operation. In nearly every case the gall-bladder was found sufficiently large to be palpated beyond Riedel's lobe, and on the surface of the abdomen during the diagnostic examination; but in quite a number of cases the enlargement was fleeting, appearing one day and disappearing for days or weeks, and then showing up again in the same manner. In two notable cases the position of the gall-bladder was quite abnormal, extending to the middle line and almost to the umbilicus. In six of the thirty-two cases the liver was markedly enlarged, especially the left lobe, and in one other case where this enlargement was present there was a cyst of the omentum in close proximity to the gall-bladder and left lobe of the liver which obscured the diagnosis. In one case, where the liver was considerably enlarged and had been pronounced cirrhotic, there was considerable ascites. Several other patients had hypostatic congestion at the base of the right lung. Not one of his patients had any discoloration about the navel often observed in calculous cholecystitis, necrosis of the gall-bladder, and rupture of the cystic duct. Most of his patients were in the fifth and sixth decades of life, but one was 72 years old, and one was 20. Two other patients were in the thirties. The most characteristic, although not absolutely uniform, symptom had been the cardiac disturbance. In the thirty-two cases which furnished most of the material every gall-bladder was found at the operation to be thick, white, and filled with tarry or porridge-like material which, by the most careful bacteriological examination in the clinical laboratory, proved sterile. Six of the gall-bladders had some adhesions, usually lace-like, but in two instances firm and strong, connecting the gall-bladder with the surrounding viscera. The operation was a simple cholecystostomy varied from the custom by the removal of a small bit of the fundus for microscopical examination. Only one of these thirty-two gall-bladders had to be extirpated on account of permanent obliteration of the cystic duct.

Medical Treatment of Cholecystitis.—Dr. WILLIAM ENGELBACH of St. Louis, in a paper on this subject, drew the following conclusions: 1. Medical treatment of cholecystitis should be directed mostly toward prevention of this disease, particularly in those affections of the gall-bladder complicating known diseases, such as typhoid. 2. Medical treatment was indicated and should be carried out with the purpose of curing the incipient mucous membrane infections of the gallbladder before these became extensive enough to produce obstruction of the cystic duct and calculi, or involved tissue beyond this membrane. 3. Gall-bladder antiseptics, such as menthol, combined with vaccine, preferably specific vaccine, probably offered the most promise for further observations upon the prophylactic and active treatment of acute cholecystitis. 4. Chronic cholecystitis was not amenable to medical treatment on account of the extensive pathological changes in the contents and tissues of the gall-bladder and the contiguous organs.

Surgical Treatment of Cholecystitis.—Dr. LOUIS FRANK of Louisville said that the prime factor in gall-bladder disease was infection, and in the treatment of gall-bladder inflammation the sequence of this infection must be remembered. The relationship between infection and calculi was a definite and a constant one. The stones themselves bore merely a causal relation to the infection, although when once stones were present they acted as a constant irritant and maintained an inflammatory condition of the gall-bladder. Furthermore, by their irritation they invited cancer. Surgical drainage was the one method of relief. In all infectious processes the necessity for drainage was recognized. The general profession needed education along the lines of early diagnosis of gall-bladder disease. The surgical indications were fully recognized by all unprejudiced and thinking men. The profession had overlooked the early symptoms of gall-bladder infection, but had sought for those symptoms indicating a more advanced pathology. Stones were only one factor in infection, and were not even a secondary sequence of infection. Too much stress was laid upon stones in the diagnosis. Drainage was the *sine qua non* of treatment. Without subsequent drainage, even though stones be removed, though adhesions be broken up, and the structures entirely liberated, a complete and perfect recovery would not take place. To effect a cure, drainage of the gall-bladder must be prolonged. It should be continued until the discharge of bile was free from bacteria. His observation had been that drainage was not carried out a sufficiently long time by many surgeons. In his own cases he maintained drainage for from two to six weeks, and even longer. As a routine he examined the bile immediately after the operation by culture and microscope. Early drainage, or drainage during the time calculi were resident in the gall-bladder, was one of the easiest, one of the simplest, and one of the most satisfactory operations, with a mortality so low as to make it urgently advised and readily accepted by the patient. Cholecystectomy was very rarely indicated in a large class of cases in which he formerly did not hesitate to remove the gallbladder. Since resorting to prolonged drainage he had been perfectly satisfied with the results obtained. He questioned the advisability of indiscriminate cholecystectomy. That it was an operation of value no surgeon would deny, but that it should be done in every case of cystic duct obstruction and in every case of empyema of the gall-bladder he was convinced was not the best surgery.

Dr. WILLIAM D. HAGGARD of Nashville thought the keynote of treatment was struck, first, in prevention in a medical way, and, second, drainage in a surgical way. Drainage in many instances should be more prolonged than was the usual custom. There were cases that had this sequence: after the drainage tube had been removed and the fistula had closed, the patient would have the same attacks of colic he had before. As a proof of the fact that early closure of the gall-bladder and interference with drainage would pro-

duce mischief, he said if one would reopen the sinus the patient would at once get relief. He had had colic occur a third time in some of his cases, and a little delay in removing the drainage tube under these circumstances would perhaps avoid the necessity of a second opening of the gall-bladder, because it was due in his judgment to the fact that the gall-bladder, after having been emptied for a number of days and suddenly called upon to retain its fluid again, naturally rebelled, and that this was an explanation of the colics. The diagnosis of chronic cholecystitis was made upon the symptomatology, or the old-fashioned stomach trouble.

Dr. Thomas Hunt Stucky of Louisville said the general practitioner could accomplish drainage in these cases in a manner that was not only beneficial to the patient, but which would be helpful to the surgeon in putting the patient in a better condition to be operated upon later. As to the use of cholagogues, if there was any irritation in the gall-bladder *per se*, if it contained any inspissated mucus, if there were retained concretions of any description or character, a cholagogue was contraindicated. He believed we could accomplish better results by giving something that was going to keep the large bowel empty, that was going to keep up a drain and by contiguity and indirect peristaltic influence produce a flow of bile. Any agent that would produce elimination from the intestinal canal would produce a flow of bile unless there was mechanical obstruction.

Dr. Fenton B. Turck of Chicago stated that experiments showed that the colon bacillus in cholecystitis became more virulent. A new accession of conditions caused an increased virulency in the microorganisms; there was a lowered resistance to the microorganisms, a loss of antibodies in the blood, and consequently increased virulence of the intestinal flora. These conditions made it possible for autolysis to take place and small ulcers were formed in the gall-bladder, the stomach, and duodenum. Many of them would heal, while others would not. Around the erosions the exfoliations formed a nidus for gallstone formation, and there took place a reaction of the mucosa, which was the inflammatory process that went on.

Dr. Robert H. Babcock of Chicago said it was up to the general practitioner to recognize the existence of chronic infection of the gall-bladder before the typical symptoms of gallstone colic, in order that the gall-bladder might be opened and drained before calculi formed and before the dangers ensued which resulted from the formation of calculi. Gallstone pain was frequently like an attack of acute indigestion, and many a case of so-called gastralgia, gastritis, or acute indigestion meant disease of the gall-bladder and the presence of stone or stones.

Dr. Daniel N. Eisendrath of Chicago said it was necessary to have a clear conception of the pathology of cholecystitis. Where the gall-bladder had become converted into a mass of cicatricial tissue incapable of contraction and incapable of doing anything else in the way of neutralizing the toxins or bacteria accompanying them, it was taken out, but this was about the only type of gall-bladder in which such an operation was done. Surgeons should not remove every gall-bladder. There were two classes of gall-bladder cases—those in which there was cholecystitis without the formation of stones, and cholecystitis with stones. Where a diagnosis was made before operation of gallstones and absolutely no stones were found at the operation except a thickened gall-bladder, with adhesions, that condition of the gall-bladder would cause just as many symptoms as the gall-bladder in which stones began to wander down the cystic duct or caused a great deal of colic or inflammation of the gall-bladder.

Dr. Albert E. Sterne of Indianapolis said it was surprising how many of these cases of infection of the gall-bladder and the viscera below the stomach came to the neurologist under the caption of neurasthenia or nervous prostration. Whenever a so-called neurasthenic patient complained of stomach symptoms persistently, a careful examination might disclose the existence of an infected gall-bladder with possible gallstones present, although the existence of stones was not always to be determined either by the *x*-ray or any other means of examination, but could be detected only at the time of the operation. It had been his experience time and again that patients had come under his care who had been treated for a considerable time systematically, but who had only recovered after surgery upon the gall-bladder had been undertaken.

The President's Address: Medical Tendencies.—Dr. Robert H. Babcock of Chicago said that so indispensable had laboratory methods become to-day that one wondered how clinicians of fifty years ago ever succeeded as well as they did in the diagnosis of any but the commonest affections. In his experience as a consultant he had become deeply impressed with the general reliance on laboratory methods shown by practitioners recently out of college, and at the same time with their ability to observe accurately symptoms or to appreciate their real significance and value as compared with the findings of the microscope or test tube. Was there not a tendency along with devotion to laboratory research and animal experimentation to make the study of pathology outweigh too greatly the application of remedies to the alleviation of disease? In how many schools of to-day did the students receive the instruction in materia medica and therapeutics they did thirty years ago? There was reason for this therapeutic scepticism, but it was a tendency which should not be permitted to grow too rank lest the art of healing be lost in the science of investigation of disease processes. Medical colleges must enlarge their clinical facilities or it might be well to return to the good old custom of each student having a practical training with an experienced preceptor. Then added to enlarged and improved facilities for laboratory and clinical instruction was a higher standard of preliminary education. In some medical colleges a degree of B.A. or B.S. was required, which requirement naturally tended to lessen the number of matriculants. Hence the effect of all this was to improve the quality, while at the same time reducing the number of medical practitioners. Nothing could be more valuable in the way of preparation for the successful practice of medicine than service in a large hospital as a so-called interne or health officer. No one could contemplate present therapeutic methods and contrast them with those of three or four decades ago without recognizing that a momentous evolution was at work. Surgery might be said to have undergone its evolution with the adoption of aseptic methods, but medicine had a far more difficult task to perform; hence its accomplishments were neither so striking nor indeed so apparent. Yet who could say that the discovery of the diphtheria antitoxin or of Flexner's antimeningitic serum and the use of autogenous or multivalent vaccines did not compare favorably in the saving of human life with any of the dazzling performances of surgery. As to a national department of public health, in all probability such a bureau or department was only a question of time. It certainly was in accord with popular education on matters of health and hygiene and sprang from the humanitarian desire for the physical betterment of the masses. Its advocates believed that a national control of health boards and public sanitation in general would be more effective than independent action along this line by state and municipalities.

Address in Medicine: Doctors and the People.—Dr. J. C. Wilson of Philadelphia said that the three professions called learned—divinity, the law, and medicine—had in modern times been curiously separated from the people at large. Even the individual members of these professional bodies, while appearing to be in many respects

very close to their fellow members of society, showed upon critical study a certain curious aloofness which became very conspicuous in the aggregate. Manifest to some extent in superficial and external things, this difference between professional and nonprofessional members of a community became impressive and significant when we investigated its actual causes. Not only were the professions separated from others, but they also differed among themselves and especially in their relation to nonprofessional persons. With medicine, however, the conditions were wholly different. The organization of the medical profession but lightly touched the people and the discipline reached them not at all. They only most remotely comprehended its aims and were incapable of a dispassionate consideration of the means by which it was striving to realize them. They were in no sense bound to it and so long as they were in good health regarded themselves as altogether above and independent of it. So far were they from being influenced by its powers to restore health to the individual and avert pestilence from the community, which must appear in every sense mysterious to them, that they formed organizations to undermine the results of scientific investigations concerning the causation and course of diseases and to prevent such investigations. Hence antivaccination societies and antivivisection societies. It was thus seen that there were many people who were wholly indifferent to the medical profession; some that were actively hostile to it. Those who were indifferent so long as they were well and who at once demanded the services of the most experienced and skillful physicians when they were injured or ill afforded material for an unpleasant psychological study. The history of medicine would be but a series of disconnected episodes were it not that it taught us that here as in other fields of human endeavor knowledge ripened slowly and that failures were the stepping stones to success. It taught us another lesson well worth the knowing, and that was that knowledge advanced by indirection. There was no reason for medicine except to prevent and cure disease, yet most of the actual workers who made this history in its earlier period appeared to have been more concerned with other matters. Medicine had thus become not only curative but also protective. No possible knowledge of effects could have given us preventive medicine. We owed this to the study of causes, and the means by which they had been and were being studied were bacteriology and animal experimentation. By the scientific and humane methods of laboratory research the nature of infection and immunity had been clearly established, the methods by which particular diseases were transmitted had been revealed, the part played by various insects as direct carriers and intermediate hosts of disease-producing microorganisms had become known, and the natural defenses of the body against infection investigated. This knowledge had been used in the cure and prevention of the infections with remarkable results in preventing suffering and saving life. Modern medicine was preventive medicine. To attain its objects, which were the protection of health and life, no effort was too arduous, no problem too difficult. Wherever disease prevailed, wherever the death rate was high, it wanted to know the cause in order that the remedy might be applied. It busied itself with water, milk, foods of every kind, and even the air we breathed. It went to the school, the mine, the factory, the shop, even to the very homes of the people to correct the faults that menaced health and life through ignorance and neglect. It invoked the law that people might be protected from themselves and from each other. It was in the highest sense educational. It invited reasonable criticism of its methods and results. It should have the interested cooperation of those who reaped the benefit of its work. There was and always would be much for it to do, always perhaps until that millennium to which the ardent disciples of Metchnikoff looked forward when, infection being ended and the forces which made for senility minimized, there would be no sickness, old age would be enjoyable, and death nothing more than a gentle turning over for a longer sleep.

Address in Surgery: The Indebtedness of Posterity to the Pioneer Surgeons of the Mississippi Valley.—Dr. Joseph D. Bryant of New York delivered the address in surgery. Among other things he said that those pioneer heroes of the Mississippi Valley who engaged in the advancement of civilization, and those devoted to the creation of novel means of medical and surgical relief, were closely akin in importance to those whom poetry and sculpture had glorified for centuries. The magnitude of the contributions of Boone and Lincoln to personal welfare, civilized comfort, and happiness in our country were well measured by similar blessings bestowed on the civilized world by Ephraim McDowell of the Mississippi Valley. In a small town in December, 1809—more than a century ago—McDowell performed the first ovariotomy recorded in the annals of our profession. The operation was successful in the full meaning of the term. The patient recovered promptly and completely, and lived thereafter in comfort and usefulness for thirty-two years. McDowell's first ovariotomy was not published until eight years after its achievement. Dr. Bryant then referred to the early work of J. Marion Sims, a most distinguished son of Alabama, and of the professional world; to Dr. T. Gaillard Thomas, from South Carolina, most eminent in his profession, and also a successful ovariotomist, and to Thomas Addis Emmett, a famous son of Virginia, and closed his address by saying that in his judgment Ephraim McDowell's contribution to the comfort and the security of the most sacred and enduring part of the family circle was of priceless value in the broadest sense.

General and Dietetic Treatment of Typhoid Fever.—Dr. George Dock of St. Louis spoke of the importance of the continued discussion of typhoid fever on account of its wide extent and continued prevalence. He directed attention to the efficient preventive treatment now available and urged that it be used in camps and in institutions or wherever bodies of people were gathered together under conditions that might make typhoid infection possible. He touched on a number of details in the general treatment, and especially on the preliminary use of calomel, showing that that could be carried out without danger of setting up dangerous diarrhea. He devoted himself especially to the question of diet. He pointed out the difficulty of drawing conclusions from small statistics, even from those running up into many hundred cases. He called attention to the anatomical processes, the importance of keeping up the patient's nutrition to the highest possible point in order to favor recovery of the anatomical lesions, and the fact that fuller diet recommended by many recent authorities did not involve any greater danger to the intestinal wall than the administration of milk. He emphasized the fact that a comparatively varied diet could be given without exciting the patient in any way, and that the morale of the patient was nearly always distinctly improved by realizing that he was not on the painfully limited diet traditionally given to seriously sick people. Various modifications of diet were described and their advantages pointed out.

Dr. Charles L. Minor of Asheville dwelt upon the question of water. He thought we ought to use all the various means of giving water to patients, of pushing water on them, having the nurses insist that they get so much water at a time and as regularly as medicine. He had for the last two years in a number of severe cases infused his patients and he had been surprised to see the wonderful effects of a bi-daily saline infusion. He could only testify as to its effect on elimination rather than the blood-pressure.

Dr. Fenton B. Turck of Chicago said it was a mistake to inject a large quantity of water into the bowel of a typhoid patient, for the reason that it overstretched he colon and increased the cramps and did not produce a true peristalsis.

Dr. John A. Witherspoon of Nashville said that in his typhoid experience sweet milk, if given at any stage of fever, and especially after the beginning of the second week, would invariably increase fermentation to the extent that one would have a great deal more gas in the abdomen and a great deal more of flatulency. Then in the stools there would be found large masses of curded milk passing through. Any diet that increased flatulency and fermentation, and that was capable of passing through the intestinal tract in a coagulated form, was not the best diet. He believed in nutrition, but sweet milk in his judgment, backed by many years of study, had no place in the treatment and dietetics of typhoid fever. If the physician would give these patients buttermilk or ordinary broths, or meat juices or extracts, he would get very much better results, and maintain the vitality of the patient better.

Dr. L. H. Montgomery of Chicago advocated soups and beef extracts, properly prepared, but he used milk as well, and buttermilk. He gave custards and poached eggs, recommended sunshine and plenty of clean sheets and bedding, and gentral hygienic rules.

Dr. Robert B. Preble of Chicago said the keynote of the discussion was individualization; that there were patients who could be fed successfully upon sweet milk without disturbance; that some could be fed nothing but water and not feel any disturbance, while there were others to whom the physician might give a liquid diet. But each patient must be handled as an individual, and any man who attempted to treat a case with a fixed diet that applied to all patients would have a lot of trouble.

(To be continued.)

MEDICAL SOCIETY OF THE STATE OF PENNSYLVANIA.

Sixty-first Annual Meeting, Held at Harrisburg, September 25, 26, 27, and 28, 1911.

SECTION ON SURGERY.

(*Concluded from page 999.*)

What Can Be Done to Preserve the Strength of Patient During Stay in Bed?—Dr. John M. Baldy of Philadelphia said that surgical patients, as a rule, were not sick in the sense, for instance, of a typhoid fever patient. Therefore, there was little call for efforts for sustaining strength after operation. The effort to force the appetite by drugs only prolonged the loss for an indefinite period. The excretory organs should be got to working actively by means of purgatives and diuretics. With a few exceptions the diet should not be limited except as to quantity. A patient kept in bed for two to four weeks on three full meals a day inevitably suffered from one or two attacks of indigestion. If the surgeon would use good judgment in deciding that an operation was desirable, would prepare his patient well, do his operation properly, and pick his nurse carefully he needed not bother much about the after-treatment.

Transfusion.—Drs. George M. Dorrance and Nathaniel Ginsburg of Philadelphia presented this paper. They said that in concealed bleeding within the abdomen or pelvis we frequently waited for the resultant syncope to arrest the bleeding. This too often resulted in loss of life. Instead of waiting and trusting to uncertainty they advised and practised transfusion. In that way it was possible to render cases apparently inoperable on account of shock suitable for operation. Instances of this were met with in gastric or duodenal hemorrhage, in hemorrhage following operation or typhoid fever or extrauterine pregnancy.

The Treatment of Tumors of the Urinary Bladder by High Frequency Desiccation.—Dr. B. A. Thomas of Philadelphia said he was strongly of the conviction that in high frequency dessication, erroneously styled fulguration, the surgeon had at his command a new measure that would challenge, rival, and surpass in effectiveness the long established methods of treatment for vesical neoplasm. It was a serious question in the mind of the writer whether or not a patient with a bladder papilloma should ever in the future be subjected to radical operation when treatment by this method was available. Two of the three cases which Dr. Thomas reported as treated by this method were entirely cured, one presenting the largest papilloma he had ever seen. The third case was at present under treatment.

Thursday, September 28—Third Day

Commission on Prevention of Venereal Diseases.—Dr. Edward Martin of Philadelphia, chairman of this commission, offered on behalf of the commission recommendations that a medical certificate of freedom from venereal or other contagious diseases should be required from the man who contemplated marriage, that one who conveyed venereal disease should be punished by a jail sentence, and that provision should be made for foci of infection so that the public might be protected. The recommendations were adopted by the society and the commission continued another year with the same personnel.

Commission on Fractures of the Femur.—Dr. William L. Estes of South Bethlehem, chairman of this commission, offered on behalf of the commission recommendations that teachers of surgery should give far more attention to the investigation of fractures and to the teaching of this important branch to their students; that, while recognizing the fact that x-ray photographs might be most misleading, they would, when properly made, furnish an indication for the proper reduction and preservation of apposition of the parts and serve as a graphic record of the fracture itself; that while treatment by means of traction enabled the patient in most cases to resume his occupation without serious detriment, yet x-ray pictures showed that absolute apposition and restoration of the proper axis of the bone were seldom accomplished; that the open method of treatment introduced such a very marked element of danger that the commission could not recommend it for general use or recognize it as a routine practice, but that in selected cases it might be employed by an experienced surgeon; that some form of traction, such as Buck's extension, seemed to be the preferable method of treatment, though Bardenheuer's transverse traction and Hamilton's apposition splints would serve a useful purpose in the majority of cases; that good functional results were obtained when the shortening was not over an inch, providing there was no inversion or eversion of the foot; that the usual methods of measurement were very inaccurate, and that the usual method of measuring should be checked by measuring from the tip of the ensiform cartilage to the internal malleolus or the patella or from the middle of the umbilicus to the internal malleolus and that in making measurements the pelvis should not be tilted and that the anterior spines should be in the same horizontal plane. The commission was continued for another year with the same personnel.

The Commission on Cancer.—Dr. J. M. Wainwright of Scranton, chairman of this commission, reported that County Societies had been urged to devote meetings to the study of cancer and that a number had done so; that six short articles adapted to lay readers had been prepared and that these would be sent to all the leading news-

papers in the State for publication; that from a report of 382 cases of cancer it was shown that only 68 per cent. of superficial cancers and 48 per cent. of deep-seated cancers were operable when they came to the surgeon; that in 39 per cent. of the superficial and 46 per cent. of the deep-seated cancers there had been a precancerous condition of a chronic irritation; that both the patient and physician were to blame for the delay in treating cancer, but that it would seem that the medical profession should be the first to show improvement in this respect.

Officers.—The election of officers resulted in the choice of the following: *Chairman,* Dr. Otto C. Gaub, Pittsburgh; *Secretary,* Dr. J. Torrence Pugh, Philadelphia.

SECTION ON EYE, EAR, NOSE, AND THROAT DISEASES.

Tuesday, September 26—First Day.

DR. WILLIAM F. ROBESON OF PITTSBURGH IN THE CHAIR.

Opening Address of the Chairman.—Dr. WILLIAM F. ROBESON of Pittsburgh said that all, no doubt, felt the practising of a specialty to be likely to make one narrow, but that he could conceive of no better way to make one broaden out than to attend such a medical gathering. By reason of the numerous special medical societies and the various State societies, the profession itself had not only improved greatly within his own brief career, but it had also broadened very much, particularly in its ethics.

Aids to Diagnosis in Otology and Their Clinical Significance.—Dr. JAMES P. MCKERNON of New York City, by invitation, presented this paper, and took up the leucocytes and the differential blood-count, blood-cultures, cerebrospinal findings, and radiology. He said that some of these diagnostic aids were merely confirmatory of the clinical evidences, while some were of the utmost value from the standpoint of a positive diagnosis.

Dr. S. MACCUEN SMITH of Philadelphia stated that it had been his custom to have an *x*-ray taken in virtually every case on which he wished to operate, especially in chronic mastoiditis.

Dr. EWING W. DAY of Pittsburgh insisted that when one had a plain case of sinus thrombosis with distinct clinical symptoms one should not let timidity keep one from operating until the diagnosis was confirmed by blood-cultures.

Dr. MCKERNON said that he had distinctly stated in his paper that the blood-cultures were merely confirmatory of the clinical evidence, and that their chief value was in cases in which there was not enough clinical evidence to enable one to operate.

Symposium on Suppurative Diseases of the Labyrinth.

Indications for Operation.—Dr. S. MACCUEN SMITH of Philadelphia said that only clinical experience and personal intuition could govern one's operative procedure in each individual case. Given a case of chronic suppurative otitis media presenting the characteristics of a latent labyrinthitis, in which there were an absence of hearing and no response to the caloric test, the indications were that the labyrinth was destroyed. Some cases of this type would recover spontaneously, but they required close watching in order to prevent further intracranial complications. This was especially true if the radical mastoid operation was undertaken. One should, therefore, endeavor to determine the exact status of the labyrinth before advising a patient to submit to such an operation. Nevertheless, on account of the lack of definite indications for operative intervention, it would seem that patients could be best served by the use of palliative methods of treatment, until definite indications for more radical procedures should become manifest. Dr. Smith was convinced that a large proportion of the fatal cases had been caused by meddlesome surgery. He thought that one was justified in operating only after one had considered the clinical evidence in each individual case.

Technique and Results of Operation on the Labyrinth.—Dr. EWING W. DAY of Pittsburgh said the indications for treatment in diffused labyrinthitis to be the relief of the violent symptoms, the avoidance of a resulting residual chronic infection, and the cutting short of the great danger of meningitis and cerebellar abscess. In considering the question of operation, the function of the ear could not be taken into account, he said. The treatment of chronic diffused labyrinthitis offered much better surgical possibilities than did that of the acute form.

Some Remarks on the Ocular Symptoms in Pituitary-Body Diseases and Results of Treatment.—Dr. GEORGE E. DE SCHWEINITZ of Philadelphia, while fully recognizing that nonacromegalic cases of pituitary body disease should present no difficulties in detection, believed that bitemporal hemianopsia and *x*-ray findings constituted the most potent features in the diagnosis. He considered the following as suggestive symptoms: unexplained amblyopia, or blurred vision, sometimes of long duration, and often at first of one eye only; a central scotoma, especially if of hemianoptic type, again often in one visual field; temporal hemianopsia preceding loss of the form sense of the affected visual field area; extraocular muscle palsy, usually third-nerve palsy, with or without exophthalmos of one or the other eye; atrophy of the nerve-head without indication of antecedent neuritis or choking of the disk; nausea and headache, the latter often violent, especially before the active degradation of direct vision and the development of visual-field defects; disturbances of the sense of smell, exaggerated tendon reflexes and (in women) amenorrhea or early cessation of menstruation. While bitemporal hemianopsia was the common visual-field defect, homonymous hemianopsia was not excluded, and might occur from backward extension of the growth with involvement of one optic tract.

Tonsillectomy: Why, When, and How.—Dr. J. LESLIE DAVIS of Philadelphia preferred tonsillectomy to any less complete operation for the following reasons: The function of the tonsil was either suspended or destroyed when the tonsil was involved in any pathological process for which even the partial removal of the gland had been recommended. To excise the free portion did not remove the cause; and in the residue of the tonsil thus amputated there still existed an inflammatory process that would result in a fibrous infiltration or be followed by a more extended necrotic invasion of the tissues surrounding the exposed place. Since the physiological function of the tonsil was compensated for after enucleation, the preservation of any part for functional effect was not necessary. When the principal indication for operation was a peritonsillar abscess, enucleation was the only operation that would insure nonrecurrence. Toxic absorption from necrosis in a remnant of tonsil tissue and the concomitant putrefaction of retained coagulated secretion and débris was almost as marked as when the whole tonsil was retained. The danger of hemorrhage and of injury to the surrounding structures was lessened when enucleation was performed. Tonsillectomy left the most perfect relation of structures bounding the tonsillar recess, and the most symmetrical readjustment of the faucial pillars. Regarding the time of operation Dr. Davis said that every tonsil sufficiently diseased, whether by virtue of its size or through absorption of its septic products, to interfere with any other normal function, either local or systemic, should be enucleated, unless the abnormality were due to an acute process that would naturally subside in due time, or offered under treatment reasonable encouragement for eventual restoration to a non-offending state. Concerning the last division of his subject, he said that the method employed by him was the simplest, since but six instruments were needed; the safest, because it produced the least possible hemorrhage; and the most satisfactory in

point of enucleating the entire tonsil without injury to the surrounding structures, leaving a normal throat so far as any perceptible function was concerned.

Dr. Eugene L. Vansant of Philadelphia remarked that the operation as now performed was much more severe than it used to be. The anesthesia was now much deeper, the loss of blood greater, and the shock to the patient worse than under tonsillotomies. Tonsillectomy should not be undertaken too quickly, because it was necessary for many of these patients to have a preliminary treatment to build them up. The surgical procedure itself should be performed rapidly; and the patient should afterward have rest in bed with a subsequent tonic treatment. Dr. Vansant thought that in some cases the tonsils were in such a healthy state that it was advisable to leave a small amount of tonsillar tissue behind. He considered anyone that performed a tonsillectomy, and left adenoid tissue in the vault, to be doing bad surgery; and anyone that removed both these, and failed to remove a nasal obstruction, to be doing very bad surgery, the fundamental object being to restore nasal respiration.

Dr. G. Arthur Dillinger of Pittsburgh said that for the last fifteen years he had been using the tonsillotome entirely, and doing a partial resection under chloroform anesthesia. This operation could be done in a shorter time, with less shock to the patient, and with no severe hemorrhage. If the pillars of the fauces were dissected away carefully, he thought that there would be few cases of small submerged tonsils in which the capsule could not be removed clean-cut. He had never been called upon to operate on the same child twice. In the last three years he had known of five deaths from hemorrhage in cases in which the complete dissection had been done and the snare had been used.

Dr. G. R. S. Corson of Pottsville agreed with Dr. Davis in his use of a small number of instruments, but said that he himself would cut out one or two of the instruments used by Dr. Davis; for instance, he saw no longer any use for the snare. He had not used it for a couple of years, and had had no serious secondary hemorrhage.

Dr. Davis stated that in most cases dangerous hemorrhage had occurred after the use of sharp knives to free the pillars, these instruments having penetrated the muscular tissue and cut blood-vessels outside of the tonsil.

The Influence of the Eustachian Tube in Purulent Otology.—Dr. M. Delmar Ritchie of Pittsburgh said that the fact that the Eustachian tube was the channel for most primary and secondary infections of the middle-ear was an accepted one in otology. Serious middle-ear infections had been brought about by pathological conditions of the mucous membrane of the tube itself. Treatment of the tubal membrane, in chosen cases, he considered an abortive measure in acute middle-ear inflammation. Curettage of the Eustachian isthmus, producing permanent closure, he believed to be a justifiable procedure in selected cases of purulent otitis media, and an imperative measure as a final step in the technique of a radical mastoid operation.

Dr. G. Arthur Dillinger of Pittsburgh remarked that the majority of otologists would spend two or three months on a new case of otitis media in trying to cure the discharge by local remedies, etc., before advising a radical operation. Curettage of the Eustachian tube, he thought, would probably be used conjointly with these measures by most men during this period of waiting. He could not see that this procedure was more dangerous than a radical operation. In entering the mastoid one was in one of the most serious localities to be found in the anatomy, and anyone doing operations on the Eustachian tube should, of course, use great caution.

Adenoids: Their Effect Upon the General System.—Dr. James J. King of Feeland said that adenoids produced deformation of the face and the palate arches. If the condition was not corrected early in life it was most difficult or impossible to correct afterward. Adenoids also had serious effects upon the general development of the child, producing well-defined changes in the blood and the general nutrition. They were undoubtedly the cause of much deafness and other serious auditory troubles, and this fact alone should be sufficient to warrant their receiving the proper early treatment.

Wednesday, September 27—Second Day.

Symposium on Tuberculosis of the Throat.

Treatment of Tuberculosis of the Larynx.—Dr. Christopher C. Sandels of Pittsburgh stated that this condition was usually secondary to pulmonary tuberculosis and required the same constitutional consideration. The proper hygienic surroundings, diet, climate, and rest, were all-important. Measures should be adopted for the control of pain and cough. Much could be done for the benefit and comfort of the patient by proper systematic local treatment.

Dr. George B. Wood of Philadelphia was sorry that Dr. Sandels had not mentioned the use of the local cautery, and said that if the lesion were not great it could be healed by the use of the galvanocautery.

The Relation of the Tonsils to Tuberculosis.—Dr. George B. Wood of Philadelphia said that about 5 per cent. of all tonsils removed showed some tuberculous lesion. Practically all patients with tuberculosis in the advanced stage had their tonsils inoculated secondarily from the sputum. Tuberculous disease of the tonsil, however, gave rise to pulmonary disease only in exceptional cases by way of the lymph channels, though such infection was possible when certain anatomical peculiarities existed.

The Anomalies of Refraction and Their Relation to Abnormalities of Ocular Balance.—Dr. Samuel D. Risley of Philadelphia remarked that it was not unreasonable to expect that, during development in an anomalously shaped orbit, not only would a great variety of modifications occur in the form of the eyeballs, which would determine their diameters, and consequently alter the radii of the curvature of the cornea, but that they would, as an anatomical necessity, also lead to changes in the length and line of direction of the optic nerves and modify the origin and attachment, the length, and the line of direction of the extraocular muscles. Great assistance in the discovery and treatment of these abnormalities, he said, was afforded by a definitely recognized standard for normal binocular vision. Having determined accurately the fault, one would often be able to correct the error in balance, and so secure comfort by restoring a normal acuity of vision for each eye and a proper binocular balance. The ideal relation would be found in two emmetropic eyes with a normal acuity of vision and a physiological range and region of accommodation and convergence.

Refraction and the Use of Cycloplegics, with Special Mention of Hyoscine.—Dr. Clarence M. Harris of Johnstown considered refraction the most important department of ophthalmology, as it affected the comfort and capability of so large a proportion of the population, and said that as a prophylactic agent it could not be overestimated. It should be adapted to the needs of the individual. Hence, a careful history taking, exhaustive methods of testing, the use of the ophthalmoscope in every case, and a close estimate of the patient's general condition were necessary. The proper use of cycloplegics he thought very important. He had come to depend upon hyoscine and homatropine. Properly used, hyoscine was equal to atropine, and in many instances superior to homatropine. It could be safely employed three or four times daily by the patient at home. Most of the cycloplegia would have disappeared in forty-eight hours. He had never had toxic

effects follow his office instillations. Distressing symptoms were frequently due to impurities in these preparations. One should first, by elaborate investigation, determine just what should be considered standard in regard to strength and purity in these drugs, and then insist on the druggist's adhering to this standard.

Dr. Wendell Reber of Philadelphia considered nothing more valuable than the repeated tests, as it took at least one test for the patient to be educated for his part in the drama. He had practically abandoned the use of homatropine. As for atropine, its use took more time than people were usually willing to give. Hyoscine had been his reliance for six or seven years. Its use allowed of more elasticity in the manipulation of the patients in the office than would that of homatropine.

Dr. Samuel D. Risley of Philadelphia stated that, while rapid cycloplegics were useful in healthy eyes, there was a very large group of eyes in which their use was not prudent or useful. Many asthenopic patients had congested, fluffy eyegrounds, and had suffered for a long time with periodical or constant headaches. Their eyes were sick, and one could not expect in a few hours to get rid of an infiltrated retina and choroid and a fluffy eyeground by any method. No patient would ever select his proper mathematically correcting glass until his sick eye was better. If one kept on using homatropine often and long enough the eye would quiet down and one could refract it correctly.

The Blackboard Evil and the Remedy—The Copybook Evil and the Remedy.—Dr. John Neely Rhoads of Philadelphia said that children and everyone else should learn to avoid glare, no matter what its source. In order to prevent the glare that came from the reflection of light from the blackboard into the eyes of the children the base of the board should be pulled away from the wall, so as to deflect the light upward. Children should never be required to copy script from the blackboard, because, in order for a child forty feet away to see them, the letters would have to have lines a quarter of an inch thick. To be in proportion the letters would then have to be five or six inches high. Besides, such copying made a constant strain upon the accommodation. The copybook evil he considered just a trifle less serious than the blackboard evil. There was a glare from the white page, and the writing of the child became less and less good as he wrote farther and farther away from the copy. The copies should be inserted in a carrier on a ruler that could be moved down the page in such a manner as to cover the last line of writing. Every child should also be taught to write and cipher without the use of his eyes. This would enable him to do a good part of his work without looking at it, and thus avoid a considerable part of the strain upon his sight.

Dr. Fremont W. Frankhauser of Reading stated that in that city the glare from the blackboard was obviated by having a light green screen dropped over the board when not in use. The glare from the copybooks, he said, might be averted by not having them made of glazed paper. A great deal of the glare in cities and towns came from the bright light striking the white concrete pavements. Lampblack should be added to the concrete in order to make a slate-colored pavement that would give no sharp reflection to any kind of light.

Recurrent Third-Nerve Paralysis, with Report of a Case.—Dr. J. Ferdinand Klinedinst of York said that his patient was a female aged fifteen years who had had since childhood annual attacks of paralysis of the right third nerve, always occurring in the early spring. The attacks always began with severe pain extending from the back to the mastoid region, over the temporal region, and to the right eye. The paralysis lasted from ten days to two weeks. No other member of the family had had similar paralysis. There was, however, a family history of migraine, and he considered it probably a case of migraine ophthalmoplegia.

Thursday, September 28—Third Day.

Orbital Diseases Secondary to Sinusitis.—Dr. Wendell Reber of Philadelphia said that all manner of extraocular and intraocular diseases were traceable to suppurative and non-suppurative diseases of the accessory sinuses, and that it would often require the most prolonged study on the part of the rhinologist to establish finally the relation. Even in the presence of seemingly negative findings intranasal treatment that would deplete the mucous membrane to the fullest extent should be instituted. In ocular conditions of apparently obscure origin he thought that no case could be said to have been properly studied until the accessory sinuses had been shown to be plainly non-causative.

The Relation of Ethmoid Disease to Orbital Conditions.—Dr. Ross Hall Skillern of Philadelphia stated that the circulatory and nervous anatomy were such as to permit of the passage of infection from the mucosa of the ethmoid cells to the orbit. He named the following as some of the pathological conditions that affected the ethmoid cells: Polypoid hypertrophies and polyps, frank or closed empyema, polypoid growth with suppuration, mucocele, and malignant growths. He stated that the infection extended by mechanical pressure, by continuity, by contiguity, and through the blood-lymph channels (toxemia). When the infection reached the periosteum of the orbital side one of two things occurred: (1) If the infecting process was not exceptionally virulent, the periosteum acted as a barrier and prevented perforation, guiding the purulent secretion anteriorly along the bone until it finally pointed externally through the upper eyelid; (2) when the infection proved too severe for the periosteum to halt it in its progress, the orbital contents quickly became involved, with the appearance of an orbital phlegmon, all of the orbital tissues being involved in one great purulent mass. If this condition was allowed to form, total loss of the eye would invariably follow. When extension through the blood and lymph-channels occurred alone, two foci of inflammation without any apparent connection were present: one, at the original seat in the ethmoid; and the other, the secondary, in some portion of the orbit. He considered it questionable whether infection from a focus of pus in the ethmoid capsule ever caused ophthalmic complications solely through the medium of the lymph—or blood-vessels; as usually the other modes of infection were at least coincident. Even in malignant disease extension through the circulation was not preeminently marked, owing to the extreme thinness of the separating partition.

Preventable Blindness.—Dr. William W. Blair of Pittsburgh remarked that the medical profession was laboring most successfully in the prevention of diseases, thus destroying the necessity for its own existence. Ophthalmology was not lagging in the rear, as witnessed by organized efforts for study and prevention. The lines of activity along which it was possible to accomplish prevention that were open to thoughtful men, he said, included hygiene and care of the eyes, ophthalmia neonatorum, trachoma, Fourth of July accidents, and industrial blindness. He thought that it would be well if the State Society should make an organized effort toward the prevention of blindness through a subdivision of the work.

Dr. Edward F. Pyfer of Norristown had been surprised at the opposition to the use of nitrate of silver existing among medical men doing midwifery and obstetrical work. At a meeting of the Montgomery County Medical Society he had tried in vain to impress upon the members the fact that a few drops of a 2 per cent. solution could do no harm. He stated that in Indiana legislation had been

adopted making the use of the Credé method almost compulsory. He suggested having two grains of nitrate of silver put in a small vial and having the obstetrician add the water at the time of using. He protested against the use of argyrol or protargol in place of nitrate of silver to combat the infection. In regard to trachoma, he said that if a small bottle of a 15 per cent. solution of acetate of copper in glycerin were give the patients, with directions to use it for an indefinite time, it would do more good than one or two applications made at the office.

Dr. Edward B. Heckel of Pittsburgh remarked that everyone doing eye work knew that blindness resulting from ophthalmia neonatorum came in many cases through the neglect of the general practitioner, and stated that the Pittsburgh Health Department made free distribution of nitrate of silver to anyone asking for it. It was put up in hermetically sealed plain glass tubes, and not colored glass; for, contrary to a prevalent opinion, it had been found that the nitrate of silver would not turn black when exposed to the light, so long as no organic substance, such as a cork, was allowed to come into contact with it. He thought that the number of cases of trachoma in this country had greatly diminished, because the government was preventing the entrance of foreigners afflicted with this disease, which had also been made a reportable one. Regarding industrial injuries, he said that many of these were due to the careless use of dynamite, and stated that while persons handling this explosive were at first careful, they later became so careless that they would even take a wagon-load of it over a stony road.

Dr. John B. Corser of Scranton said that in his section of the State more eyes were lost from the pieces of copper thrown from copper capped dynamite cartridges than in any other use of dynamite. Children would find these where they had been carelessly left by the workmen, and explode them innocently. The pieces could not be removed unless they could be seen and taken out by means of the forceps. He thought it would be well for some of the members to interview the makers of these cartridges and see whether they could not make them of steel or iron.

Dr. Clarence M. Harris of Johnstown thought that trachoma was on the increase in his locality, where the people lived crowded together, the beds never being long enough unoccupied to become cold. One case of the disease might infect a whole house. The municipal authorities, he said, should compel these people to live right. Very few of these cases were reported. Indeed, the health officers did not know what a physician was talking about when he reported a case of trachoma.

Dr. Wendell Reber of Philadelphia then offered the following resolution, which was adopted:

Whereas, it has been increasingly shown that much of the blindness incident to injury and disease is largely preventable; and, *whereas*, the intelligent resort to ordinary, every-day means and methods in the manufacturing establishments of the State of Pennsylvania would greatly reduce the number of partially and wholly blind persons, thus relieving the State of a grievous burden: Be it, therefore,

Resolved, That the Section on Eye, Ear, Nose, and Throat Diseases of the Medical Society of the State of Pennsylvania recommends to the general body of the society that a permanent committee be formed, to be known as the Committee on Prevention of Blindness and Conservation of Vision, to act in conjunction with the Pennsylvania Association for the Conservation of Vision and the other societies working in the same direction.

Dr. Reber was appointed a committee of one to present this resolution to the general body.

Officers.—The following officers were elected for the ensuing year: *Chairman*, Dr. Wendell Reber, of Philadelphia; *Secretary*, Dr. Clarence M. Harris of Johnstown

NEW YORK ACADEMY OF MEDICINE.

Regular Meeting, Held November 2, 1911.

The President, Dr. William M. Polk, in the Chair.

The scientific business was held under the auspices of the Section on Surgery.

Report of the Committee on Hospital and Municipal Budget.—The Committee of the New York Academy of Medicine on Hospitals and the Municipal Budget (*President*, Dr. Charles L. Dana; *Secretary*, Dr. James Alexander Miller) was formed by the consolidation of two committees created by act of the Council and appointment by the President. The work of this reorganized committee had been the investigation in this city of hospital conditions. It was to keep the profession informed in regard to hospital needs, organization and progress and to cooperate with the library in securing hospital literature; it was also to investigate the conditions and needs of those departments of the city which controlled the public hospitals, viz., the Health Department, the Charities Department, and the Bellevue and Allied Hospitals, so that the committee could with proper data appear before the city authorities and help in securing needed or in opposing unwise appropriations, so as to increase the efficacy of our city's hospitals. All this was to be done on condition that such investigation and help were desired. The work of this committee should not be done without the aid of paid and efficient labor and through the generosity of a friend such help was obtained and work was begun in May, 1911, and had gone on steadily ever since. After a conference with the President of the Borough of Manhattan and with the Board of Estimate and Apportionment, the Committee was organized as follows: 1. Subcommittee on the Department of Public Health with Dr. Huddleston as Chairman. 2. Subcommittee on Bellevue and Allied Hospitals with Dr. Thompson as Chairman. 3. Subcommittee on the Department of Charities with Dr. L. Williams as Chairman. A permanent Executive Committee was appointed to take charge of and superintend the active work. This committee consisted of the President and Secretary of the General Committee and the Chairmen of the three special committees. The Subcommittee on the Charter was continued. With this organization much useful work had been done during the past six months. With the cooperation of the Health Department a study of its hospitals was made, the results of which were embodied in a report with recommendations and suggestions which had been submitted to the Council. The recommendations and advice of this Committee were asked and given to the city authorities and were effective in securing for the Health Department means for enlarging its work, for establishing new hospitals, and for adding to its facilities for tuberculosis patients. Similar investigations were made of the hospitals and of the Charities Department and a report was submitted to the Council. The Subcommittee on the City Charter drew up arguments against the hospital organization scheme of the proposed new City Charter, and they were presented to the Assistant Corporation Council and brought to the attention of other city officials interested in the revision of the Charter. The arguments and the position of the Committee were formally approved by the Board of Governors of Bellevue and the Allied Hospitals. Through the activities of the subcommittees a great deal of valuable statistical matter had been gathered and put at the disposal of the Committee and the Academy of Medicine. They felt that the work was appreciated and its position as an important organ of opinion acknowledged by the officers of the City Departments. Financial officials of the city and others in authority had expressed the opinion that they needed and desired the views and advice of medical men on questions of hospital and public health

policy. It was proper that such a body as the New York Academy of Medicine should have a special body to whom the city could apply. They owed this as a public body to the public good. The committee also felt that if its paid executive committee were continued it could and ought to assume the work of a Council on Hygiene, or a Committee on Public Health, since the Section on Public Health had been discontinued. It therefore asked for this enlargement of its activities.

The Council approved of the Report of the Committee and voted to grant to it the enlarged powers which it asked and also voted that the report be read before the Academy and published in the journals.

Proposed Program of the Committee of the Academy of Medicine on Public Health, Hospitals, and Budget.—1. **Public Health.**—It was proposed that the object of this branch of the work be as follows: *a.* To maintain a bureau for the collection of facts in regard to public health, sanitation, and hygiene. *b.* To endeavor to establish an active cooperation with all public health activities in the city. *c.* To keep the medical profession advised of public health conditions. *d.* To render to the public authorities and to the community at large an authoritative medical opinion on public health matters. This was to include frequent conferences with officials of various city departments, the holding of public meetings, the giving of lectures, the distribution of literature, and other methods of publicity. *e.* To undertake and suggest special researches looking to the solution of vital public health problems, such as the investigation of industrial diseases, etc. *f.* To make a comparative study of methods and results of public health activities in other cities, both in this country and abroad. *g.* To cooperate with the Library Committee in maintaining the literature in the Academy Library upon the subjects of public health, sanitation, and hygiene in a high degree of efficiency.

2. **Municipal Budget.**—The object of the work in this direction was as follows: *a.* To utilize facts obtained by the study of public health and hospital conditions for practical application in the preparation of the annual municipal budget. *b.* To assist actively the various departments of the city government which related to public health and hospitals in the preparation of their tentative budgets. *c.* To take an active part in the budget hearings before the Board of Estimate and Apportionment.

3. **Hospitals.**—The work in respect to the hospitals would be as follows: *a.* A study of hospital and dispensary conditions in New York City, including public and private institutions in all the boroughs. This study to be made from the standpoint of construction, equipment, administration and medical efficiency. *b.* To plan for the future development of hospitals and dispensaries according to the distribution of population and to further the efforts already being made to raise the standards of dispensary work. *c.* To undertake the comparative study of hospitals and dispensaries in other cities, both in this country and abroad. *d.* To cooperate with the Library Committee in establishing and maintaining a section in the Library of the Academy for the collection of all forms of literature relating to hospitals and dispensaries

The Academy voted to adopt this proposed plan of work.

Certain Phases of the Surgery of the Spinal Cord and Spinal Paths.—Dr. Charles H. Frazier of Philadelphia presented this paper. He first considered the treatment of spasmodic torticollis and occipital neuralgia. One of the characteristic features of the first three cervical nerves was the free anastomosis not only between each of the posterior divisions one with another but between the anterior and posterior divisions as well. Recurrence of pain or motion was inevitable unless all three divisions of the first, second, and third were resected. Because the muscles at the nape of the neck concerned in drawing the head backward and rotating it, with the exception of the trapezius, were supplied by the posterior division of the cervical plexus, resection of these nerves was suggested as a means of relieving, if not curing, spasmodic torticollis. The violent contractions of this distressing condition were favorably influenced by a peripheral operation. Dr. Frazier had had experience with six cases, two of which were reported as cured, while in the remaining four the improvement had been so decided that the operation was more than justified. He, therefore, recommended this operation with perfect propriety. Before undertaking the operation the surgeon should be perfectly familiar with the anatomical relations because the field of operation was one seldom approached and the isolation and identification of the nerves in question was not free from difficulties. The technique which he recommended was different from that of Keen. The anatomical guide to the first three cervical nerves was the obliquus inferior muscle which formed the base of the suboccipital triangle, which might be identified by its points of attachment and insertion in the transverse portion of the atlas and spine of the axis. The first and second nerves emerged just above, the third just below this muscle. To reach this, the deepest of five layers of muscles, a curved cutaneous incision was made transversely from the mastoid process to the median line, and one inch below this incision the intervening muscles were divided down to those of the suboccipital triangle where the cervical nerves might be found, and were resected from their point of exit from the spinal foramina as far as they could be traced, usually for 6 or 8 cm. In closing the wound no attempt should be made to suture the divided muscles, but only the aponeurosis and skin. The extraction of the nerves by the Thiersch method was a dangerous procedure, as the cord might be damaged or injury to the origin of the phrenic nerve might result in respiratory failure. Dr. Frazier had removed the ganglion of the posterior division of the occipitalis major in three instances for the relief of occipital neuralgia and this was as absolute a safeguard against its recurrence as the removal of the ganglion of Gasser for neuralgia of trigeminal origin. Dr. Frazier cited a case of brachial palsy resulting from an injury in which he felt that operation on the plexus itself offered little hope of relief and he therefore did a laminectomy, and upon opening the dural sac the fifth, sixth, and seventh cervical roots, both anterior and posterior, were found wanting and two defects each the size of a dime were seen in the lateral aspect of the dura. In operating he resected the eighth cervical and first thoracic. The pain was alleviated to a marked degree. This case was cited because it had a distinct bearing on the effects of root resection. With respect to the results of root resection it was quite evident that the severance of every connection between the upper extremity and spinal cord, except through the intercostohumeral, representing the second thoracic root, did not render the patient as free from pain as one would have expected. In this case of brachial plexus palsy the gross lesion within the spinal canal led him to suspect that in the avulsion of the root they had a satisfactory explanation for the pitiful end results with or without operation in the majority of brachial plexus injuries. Where an attempt was made to restore function by nerve suture or anastomosis the results were either negative or but feebly effective. In most instances the operation had revealed a definite lesion of the plexus and it seemed possible that motor or sensory, one or more, had been avulsed. He submitted this as a contribution to the pathology of brachial plexus palsy for their consideration and discussion. The routine procedures were anything but satisfactory. Before any material advance could be made in

this field they must investigate the topographical structures of the individual nerve trunks as a means of intelligently selecting and planning anastomosis and must resort to more ingenious methods than were now in vogue. In regard to fractures and fracture dislocations of the spinal cord Dr. Frazier said that personally he favored early operation. The preliminary report of Dr. Allen seemed to indicate that only by early operation could they hope to save the cord from the effects of the traumatic effusion which formed so rapidly and proved so disastrous. Circumscribed serous meningitis responded to surgical therapy, and the sooner the operation the better would be the results. Numerous instances could be cited that would emphasize the fact that the end results of root resection were very variable. In some there might be a partial, in some complete anesthesia, transitory or permanent; in some hyperesthesia, in some no disturbance of sensation at all. These widely varying phenomena would seem to throw some doubt upon the present conception of the pathways of all afferent sensations and should open up a field for investigation. A communication from Kidd in the *British Medical Journal*, August, 1911, in which he reviewed a large amount of evidence which he had collected concluded that afferent fibers, in some cases algetic, in others reflex, existed in the spinal ventral roots of man and many other vertebrates. He went so far as to advocate the division of the ventral as well as the dorsal roots except in the case of the third and fourth cervical roots. The matter of posterior root resection for spasticity or athetosis was a vexing question. He had operated upon six cases of various ages with various lesions. While the number of operations was not large the series was thoroughly representative in every way, including ages from five to forty-three, lesions of from one to ten years' duration, of both spinal and cerebral origin, some with and some without athetosis, a moderate spasticity and one of very high degree. From a survey of this material it might be said that in certain cases and under certain circumstances resection of the sensory roots of the spinal cord relieved spasticity, that this relief, so far as they could judge, was not transitory, that the treatment was more efficacious for the lower than for the upper extremities, that the restoration of function would be accomplished in an inverse ratio to the amount of muscular weakness, and that the degree of muscular weakness could not be estimated before operation. In this series the spasticity was relieved in three of the four paraplegic cases; the fourth, a case of cerebrospinal, was only partially relieved. The two cases involving the upper extremities were disappointing, and this brought up the question as to the number of roots to be cut. The section of a given number of roots was not followed by uniform results. In selecting the roots to be cut two of every three roots supplying a given group should be chosen, and the roots selected would depend upon which groups were most affected. Ordinarily for the upper extremity in severe cases of spasticity the fourth to the eighth cervical and the first dorsal should be selected; of these the sixth was the most essential. In milder cases the fifth, sixth, and eighth cervical and the first dorsal would suffice. For the lower extremity, in mild cases, the third and fifth lumbar and first and second sacral. In more severe cases the second and fourth lumbar and first and second sacral. Van Gehucten had suggested that the resection be restricted to a limited number of radicular filaments of only three roots. This might be applied with advantage to spasticity, but it was doubtful if it could be applied with advantage to operations designed to relieve pain. A point to be emphasized was the importance and necessity of a course of after-treatment. Secondary anastomoses, gradual extension of contracted limbs, reduction in locomotion, and passive movements must be included in the program. Although time would not suffice for an extended discussion of end results, it might be said that the effect of the operation was more gratifying the further down the cord they went. When the roots of the lumbar plexus were involved the effect was comparatively uniform and usually permanent. After root resection temporary paralysis of the lower extremities and bladder had been observed; this was probably due to trauma to the cord. In his own case where this had occurred the cord had been gently retracted in order to bring the roots of the opposite side into view; this was an error in technique. In regard to laminectomy there seemed to be an over-apprehension regarding the opening of the spinal canal and the difficulties and dangers seemed to have been exaggerated. As a routine procedure it was both wiser and safer to complete the operation at one sitting. The danger of infection was less by one half, and one anesthetization was certainly preferable to two. Another bugbear in the minds of many operators was the escape of cerebrospinal fluid and the accompanying danger of infection. Accurate closure of the dural incision with a No. .00 continuous catgut suture mounted on a fine needle should be a sufficient safeguard against leakage. As an additional safeguard the line of incision in the skin should not correspond to that of the fascia and muscles. For this reason he preferred a semilunar incision in the skin, and after reflecting the flap a longitudinal one in the aponeurosis and muscles. The aponeurosis was closed also with continuous catgut with double strand No. 1, and drainage was also inserted down to the dural sac and brought to the surface through a stab wound, never through the line of cutaneous incision. Should the flow of cerebrospinal fluid be established, the foot of the bed should be elevated well above the head to counteract the effect of gravity. The active bleeding that sometimes followed the separation of the muscles from the spinous processes was effectively controlled by tampons of gauze wrung out of saline solution almost boiling. Hemorrhage from the exposed surfaces of the cut laminæ was readily stopped with Horsley's wax. To prevent the escape of the cerebrospinal fluid during operation the pelvis should be elevated. In discussing the advantages of unilateral and bilateral methods Dr. Frazier said he had found that the removal of two alternate spinous processes, with their corresponding arches, leaving the others intact, was a very satisfactory compromise between the unilateral and bilateral methods. In the identification of the roots he had been guided entirely by the point at which they left the dural sac with relation to the spinous processes.

Results of Post-Mortem Examinations in Cases of Cranial Injuries and Simulating Conditions.—Dr. Otto H. Schultze said he wished to offer some results of his work which he thought might be of use to the operating surgeon. It was very important to distinguish between a fracture of the vault and a fracture of the base of the skull; also between a direct or an indirect fracture. The skull might be looked upon as a bone contained in a firm capsule and one, therefore, that would be fractured in a definite direction. The line of fracture depended in large part upon the pole struck. There was what he called the "bursting fracture." The one point of importance regarding this fracture was that it occurred along the line of the greater curvature occupying a segment of the larger sphere; this was where the bursting was liable to occur, since this was the weak point. So far as the bursting fracture itself was concerned, its only actual value for the surgeon was the question, did the line of fracture pass across the larger branches of the meningeal artery? The most important thing which concerned the operating surgeon was, did the line of fracture cross the branches of the middle meningeal artery, an area that was most vulnerable. So far as the location of the epidural clot was concerned, it occurred posterior to the branches of the middle meningeal artery; the most common cases

occurred low down in the middle fossa. The posterior branches of the middle meningeal artery, however, were not so vulnerable. With regard to an epidural clot it was very important to know the general form of the skull, to locate the particular portion of the skull that was struck, and to follow out the most probable line of bursting fracture. Clinically too much attention was placed on the hemiplegia. The hemorrhage, as a rule, was a gradual one. If a patient fell upon the back of his skull the bursting fracture would be on the same side as the injury. A bursting fracture preferred to take the curve of a greater sphere rather than that of a smaller one. As to laceration of the brain as a result of contrecoup, the result of a blow received on the side opposite, in not a single instance was this directly opposite; they now had to abandon the old explanation regarding force by contrecoup, or the actual wave of the force across the skull. Many cases of laceration, however, could be predicated directly if one knew the part of the skull struck. The part of the skull that was struck was compressed; the equator was enlarged at right angles to the axis of compression, and the laceration occurred at that point. Opposite the pole struck the brain was called upon suddenly to occupy an area that formed a larger sphere, and the area of laceration could be mapped out. With regard to pachymeningitis hemorrhagica interna, a point of practical importance was the mistaken impression that there was an occurrence of bloody cerebrospinal fluid. The presence of blood in the cerebrospinal fluid did not mean fracture of the skull primarily; it meant a laceration of the cerebral cortex. In epidural hemorrhages no blood appeared in the cerebrospinal fluid. In central hemorrhages the patients were practically dead before the blood got to the cerebrospinal fluid.

Dr. M. Allen Starr said they were all indebted to Dr. Frazier for his summary of work done in the various departments of spinal surgery; it was just as important that they should hear of results that were negative as it was that they should hear of results that were favorable. It seemed to him that as an outcome of that portion of the paper which interested him greatly, the portion in regard to the section of the spinal nerve roots, the conclusion to be drawn was that very little could actually be promised in an individual patient in the relief of pain. While, in persons suffering excruciating agony, they were inclined to operate, it was well to realize that they could not promise definitely any great result from the operation. While they might feel justified in dividing the posterior nerve roots in cases of pain, and particularly in cases of gastric crisis in tabes, the results would be problematical. This was the position he said he must take after his experience in a few cases operated upon by Dr. Hartley. He regretted to say that in three cases, of which he had personal knowledge, no relief attended the operation. He had been exceedingly disappointed in the results of section of the posterior nerve roots in the spinal canal for the relief of intractable neuralgia of the trunk in one case he remembered. He had had no personal experience in regard to this operation for the relief of gastric crisis in tabes, but it came to his knowledge while abroad that in three cases (two in London and one in Edinburgh) the results of this operation had been negative. In the two London cases four consecutive dorsal nerve roots had been cut for the relief of gastric crisis, and nothing had been accomplished in either case. Nothing was accomplished in the Edinburgh case either. Therefore, it seemed to him that the operation for the relief of pain by intradural section of the nerve roots was one which perhaps in the future might yield favorable results, but at the present time they could not recommend it to their patients. Dr. Starr said that his experience regarding operations for the relief of torticollis was not favorable: he had seen a number of operations done, division not only of the spinal accessory nerve, but also of the posterior nerve roots, and he had failed to see any favorable results follow. Several years ago he was particularly interested in this subject; at that time he was President of the American Neurological Association, and this subject was up for discussion at one of their annual meetings. The consensus of opinion of a number of surgeons from all over the country, men like Maurice Richardson of Boston, Charles McBurney of New York, William S. Halsted of Baltimore, was that this operation for torticollis was almost always a failure.

Dr. Charles A. Elsberg said that he was much interested in Dr. Frazier's paper, especially because it seemed to him that in the study of diseases of the brain and of intracranial surgery the spinal cord and its diseases had been somewhat neglected. More attention should be paid to diseases of the spinal cord and their surgical treatment. During the past few years the interest in spinal surgery had been somewhat stimulated by the publications of Foerster, of Breslau, and his suggestion to cut the posterior nerve roots for spasticities. This idea had, however, already occurred to a number of American neurologists. There were a number of affections of the spinal cord which could be relieved and cured by operative treatment. With regard to meningitis serosa, he recalled one case in which such a diagnosis had been made by him from the operative findings, but he was still in doubt whether the diagnosis was correct, although the patient was entirely relieved by the operation. Perhaps there were a number of instances in which the pia arachnoid was not opened at first and in which the cerebrospinal fluid was seen to flow up and down with each respiratory movement which might be looked at as cases of localized serous meningitis. The opening of the pia allowing of the escape of fluid from beneath it might even be followed by great improvement, but that would not be a proof that a localized collection of fluid had existed in the case. After the bilateral removal of the laminæ with the spinous processes great improvement might follow the operation itself. In a number of cases in which he had found nothing to explain the symptoms of spinal tumor that had been present, he had removed five or six laminæ, and the patients had improved in a most astounding manner, several being entirely cured. He recalled several instances of sclerosis in which a laminectomy had been followed by a remarkable improvement in motor and sensory symptoms for a time. He was not prepared to say whether this improvement was the result of circulatory changes or of the decompression. He agreed with Dr. Frazier that in most instances a bilateral laminectomy was preferable to a hemilaminectomy. Dr. Elsberg said that he was much interested in what Dr. Frazier had said about paralytic ileus after laminectomy. He had had several patients who suffered from marked abdomenal distention for several days after a laminectomy in the upper dorsal region which gave the patients much discomfort and which was difficult to relieve. He never looked upon the condition as one of paralytic ileus because the patients never vomited, they only had a marked intestinal distention. He agreed with what the other speakers had said in regard to the ineffectiveness of posterior root section in many cases of intractable pain, although some of the patients were entirely relieved by the operation. Up to the present time there was no way to distinguish between the favorable and the unfavorable cases for the operation.

Dr. Pearce Bailey said that one of the most important points regarding this operation was the question of the relief of pain and, if he remembered correctly, when Dr. Dana first proposed the operation and Dr. Abbe performed it, it was for peripherally situated lesions; section of the posterior nerve roots served to relieve the pain. He remembered one case that Dr. Abbe operated on by making a

section of the posterior nerve roots for pain that was intractable, being the result of a sarcoma of the brachial plexus. The pain had existed a few months only; after the section the pain stopped immediately and did not return during the life of the patient. It seemed to Dr. Bailey that the question of whether the pain was peripheral or central in origin was important. If the pain was peripheral, after a certain length of time it seemed to become cortical, and then any section of the posterior nerve roots was useless. He recalled a case he saw one year ago, a patient on whom Dr. Taylor operated; there was a rupture of the brachial plexus and injury to the cervical nerve roots, and as the arm had been amputated at the shoulder the case appeared eminently fit for posterior nerve root section. The operation was delayed six months after the injury; the section of the posterior nerve roots which supplied the painful areas gave negative results as far as the relief of pain was concerned. Dr. Bailey agreed with Dr. Elsberg in regard to meningitis serosa; there was no pathological basis for the existence of a circumscribed serous meningitis. The recoveries or improvement of the symptoms following laminectomies were often remarkable. In one case he remembered, a man presented himself with symptoms of a spinal cord tumor which had existed for three years; he had the knee jerks, terrible pains in the legs, and some anesthesia. A double laminectomy with decompression was done, and there followed an immediate relief of the symptoms, and this relief had been permanent now over one year. There were a number of patients at the Neurological Institute with distinct focal symptoms of spinal cord lesions in whom at operation no tumor was found, but in whom immediate relief of symptoms followed. They had come to the conclusion that oftentimes as much relief followed the opening of the spinal canal as in opening the abdomen in cases of tuberculous peritonitis. Many cases of relief in serous meningitis might be explained on that basis. Sir Victor Horsley's report of relief following operations for syphilitic lesions was possibly due to the same cause. In regard to the operation for the relief of spasticity by section of the posterior nerve roots, he had tried this in one or two cases where the spasticity was due to multiple sclerosis. The results were unfortunate, and they never again proposed to recommend this operation in this disease; the relief of the spasticity might be for a few weeks, but after that in both of the cases the disease progressed, and at the end of three months the patients were in a more serious condition than before the operation. With regard to Dr. Schultz's paper, he asked if he would tell them something about the condition, which puzzled clinicians very much; in any local collection of fluid following an injury was there any benefit to be derived by operation or lumbar puncture?

Dr. Alfred S. Taylor said there were a number of things in the paper that particularly interested him. He had had only one case of torticollis, and he had attempted to apply posterior nerve root section for its relief; in that case the posterior nerve roots of the upper three cervical nerves were divided at the first operation, and the spinal accessory was divided peripherally at the second operation. There was marked relief, but not a complete cure of the condition. He did not know whether the relief was from the posterior nerve root section or whether there was a psychical influence; it might be both. With regard to section of the posterior nerve roots for the relief of pain, there were a certain number of cases that could be relieved, and he reported one case that was particularly interesting. This was a man who had his left arm and shoulder almost knocked off, with, of course, complete rupture of the brachial plexus. The arm was amputated at the shoulder by the doctor whom he then consulted. The terrible pain he experienced immediately after the accident never left him, and the pain was referred to the missing arm. He came to New York and was operated on for the relief of this pain. The posterior nerve roots of the lower four cervical and first dorsal nerves were divided completely and this was followed by absolutely no relief from his pain. Recently there was reported an observation just referred to by Dr. Frazier that sometimes sensory fibers ran to the cord through the anterior nerve roots. This patient submitted to operation again two days ago; two days after operation, *i.e.* to-day, he told him that he experienced less pain than he had for many months; whether this relief would be permanent or not he could not tell. The first day after operation the pain was as bad as ever. The interesting thing was that two days after the operation the pain was less than it had been for several months. There appeared the question of the psychic influence, but the improvement on the second day after operation seemed to Dr. Taylor to do away with the probability of the pain being psychic. It had been Dr. Taylor's fortune to operate upon thirty cases of brachial birth palsies in which there were many lesions external to the spinal canal. After nerve repair there was such a distinct improvement in the great majority of cases that one must consider that there was present no spinal lesion. In two or three cases where there had been found comparatively slight lesions in the brachial cords, but where there was an extensive paralysis, little or no improvement followed the operation. In these cases there was also an extremely marked atrophy, an atrophy more extensive than the distribution of the paralysis in the extremity. It seemed to him that by observing the relations between the atrophy and paralysis present in the arm one might be able to distinguish between those cases where roots have been divulsed from the cord and those where the injury was entirely in the external brachial plexus. He had had two cases of gastric crisis; in one patient the condition had been present more than one year. The seventh to the tenth dorsal posterior nerve roots were divided on both sides. There was complete relief. Later he developed crises in his bladdr; those lasted but a short time and gradually disappeared. The second case was a confirmed morphine taker; two to four days after the operation there seemed to be considerable relief of the gastric crisis and the morning vomiting; then the pain and vomiting returned. This case was considered to be a flat failure. From his personal experience he could say that in 50 per cent. there was no return of the gastric crisis after operation. He noticed that some German authorities gave from 80 to 90 per cent. of cures, which was much higher than the returns in this country. It was very important in these cases, if anything was to be done by operation, to do the operation before they became morphine eaters. Very often it was difficult to identify the exact nerve roots chosen for section, and he had adopted *x*-ray pictures with metal markers as most reliable. His experience with spasticity embraced fifteen cases. The work in the upper extremity was not nearly as satisfactory as the work in the lower extremity. In one arm case there was a considerable amount of pain in the contracted muscles; the pain was relieved by operation, but the spasticity was only slightly relieved. In work in the lower extremity there usually followed relief of both the pain and the spasticity. A very important thing in these cases was the after-treatment. It was as necessary to educate these patients in the use of the muscles as it was to teach children to walk. It was only by careful and systematic training over a long period of time that one could hope to get the best results after operation by root section. With regard to the number of roots to be divided Dr. Taylor said he preferred to divide portions of all the roots in their order of origin rather than to divide two whole ones and then to skip one. The results were equally good and the technique was simpler, particularly in the lumbar region. With regard to the technique he

said that his interest was largely in the unilateral laminectomy. He had operated upon thirty cases. Four or five cases had been operated on, exploring for suspected tumor; one revealed a tumor which was later removed by Dr. Elsberg during his absence from the city. He thought that the secret of laminectomy for cutting the nerve roots on both sides without traumatism to the cord was in bevelling the bases of the spinous processes. They had tried to minimize the amount of blood left inside the dura at the end of the operation. A point in the technique was this: since the roots contained small vessels which bled on cutting and blurred the remaining field, he took a clamp, crushed the root, and then divided it through the crushed area. The presence of blood would not interfere then with the cutting of the remaining nerve roots.

Dr. James Ramsay Hunt said that in the operation for section of the posterior nerve roots it had been suggested that only a partial section be made; it seemed to him that this would be an error, as there would result a false neuroma which would cause a focus of irritation. As the object of the operation was to do away with afferent impulses through these roots, it seemed to him that a complete section only of the root would accomplish this end. He was in accord with Dr. Starr's statement regarding the inadvisability of operation for spasmodic tic. He had had two cases in which section of the posterior branches of the second, third, and fourth cervical nerves was done, and with only a temporary improvement. The operation was so severe and the result so poor that the patients became discouraged and were unwilling to continue further treatment directed toward the correction of the underlying mental state, which, after all, was the essential motive of operation. He had seen cases of meningitis serosa; at operation no tumor was found, although the symptoms were indicative of tumor. Such accumulations of cerebrospinal fluid were usually found in organic diseases of the spinal cord: in central growths of system disease, and this might explain some of the cases

Dr. Frazier said that he was glad that Dr. Starr approved reporting the unsatisfactory results which followed the cutting of the posterior nerve roots for the relief of pain; he was in accord with his views. He thought that it was the duty of every surgeon to publish records of his failures, especially in the cases of the newer procedures. Sometimes a successful case was reported and many operations would follow by men who had no experience whatever in that particular class of cases. He thought that it was incumbent upon one to report failures as well as successes. Dr. Frazier said that he did not feel that he was at all justified in taking back what he had said regarding the treatment of torticollis, for his results had been very good. The operation was not an easy one and, in his opinion, was more difficult than operations upon the Gasserian ganglion. Unless the operation was done thoroughly, the best results would not be secured. He sympathized with what had been said regarding the pathology of meningitis serosa, the pathological findings at the time of operation. He regretted not having had a larger experience in this condition, and what he had said regarding it was influenced by the experience of Dr Horsley, for whose work all had the greatest admiration and in whose opinion they all placed much confidence. With regard to the relief following section of the posterior nerve roots for crisis, he believed that they should take a more conservative view. He felt, however, that in certain cases the results justified the operation It was interesting to know, however, that recurrences did take place after the operation, but it was not, strictly speaking, a recurrence, for this reason: whereas the pain was due to the gastric crisis of tabes before the operation, after it returned oftentimes in other parts, such as the bladder or the intestine. The intestinal or the bladder crisis came on some time after the operation for the gastric crisis. He thought that if they could get these cases early enough, before they had acquired the morphine habit, they were justified in the more desperate cases in doing a section of the posterior nerve roots. He agreed with what was said in regard to doing a partial section of a large number of nerve roots rather than a section of a limited number of roots. With regard to what Dr. Schultz had said, his observations were immensely interesting to him because so little opportunity had been afforded him to see such a considerable amount of material. It was interesting to hear how he was enabled to localize the clot, to determine on which side of the brain was the epidural clot, and also to hear what he said in regard to operations for the relief of cerebral compression and the saving of lives in cases of cerebral contusions. In the consideration of these pathological conditions they should bear in mind the rapidly forming cerebral edema. One could not stop or stem this pathological process. For this reason he believed that operations for cerebral decompression should not be recommended as a routine procedure in this class of cases.

Books Received.

The Medical Record *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

Conduct and Its Disorders. By Charles Arthur Mercier, M.D., F.R.C.P., F.R.C.S. 277 pages; cloth; price $3.25 net. The Macmillan Company, Ltd., London, Publishers

Diseases of the Ear. By William Milligan, M.D., and Wyatt Wingrave, M.D. 596 pages with 293 illustrations and 6 colored plates; cloth; price $5.00 net. Macmillan & Co., Ltd., London, Publishers.

THE TREATMENT OF TUBERCULOSIS AND OTHER DISEASES OF VEGETABLE PARASITIC ORIGIN BY DEEP MUSCULAR INJECTIONS OF MERCURIC SUCCINIMIDE.

A THEORY AND THE RESULTS OF ITS APPLICATION IN TWENTY-SIX CASES.

BY BARTON LISLE WRIGHT, M.D.,
SURGEON, UNITED STATES NAVY.

SINCE reporting my case of acute miliary tuberculosis of pulmonary type, treated as indicated above, in the *New York Medical Journal*, March 18, 1911, I have improved the method so that I now believe more constant results can be obtained in the treatment of all cases of tuberculous infection. For a long time I have also believed that any of the group of diseases classed as infectious granulomata could be successfully treated in this way, and more recently I have entertained this belief in relation to all other diseases of vegetable parasitic origin. In order to make myself clearly understood it will be necessary to cite the now well known work of Ehrlich, as follows:

Ehrlich's Theorem.—Every specific microorganism has a specific chemical affinity, which when found and injected (intramuscularly or intravenously) into the infected host will cure the specific disease. This may be expressed by a chemical formula as follows: (Specific antigen + specific chemical affinity) + antibody + complement = complement fixation (cure). As I understand it Ehrlich's first proof was obtained by the treatment of mice infected with trypanosomes, in which, after a time, he was able to cure the disease by one injection of trypan red, the curative action of which may be shown by the following chemical formula: (Trypanosoma + trypan red) + antibody + complement = complement fixation (cure); and proven by the following geometrical formula: *X* cases of trypanosomiasis + trypan red = *X* cases of trypanosomiasis cured.

During his experimental work he discovered that, while a single large dose would absolutely destroy these organisms in the infected host, smaller doses frequently repeated not only would not destroy them, but in time rendered them immune to the action of the curative agent (chemical affinity), and that this immunity was conferred upon their offshoots. The importance of this discovery is only second to the brilliant conception of his theory, for upon it depends success or failure in the treatment of disease along these lines.

As I said in my first paper on this subject, in 1908, the value of mercury in the treatment of tuberculosis came to me by accident; had I been familiar with Ehrlich's theory and work at that time I am convinced that many of my own failures and those of others would probably have been cures. Until the present I never used initial doses larger than 0.013 gram (1/5 grain), yet even with this small dose I accidentally secured the complete or nearly complete parasitotropic action of the chemical upon tubercle bacilli in a number of cases, resulting in the excellent and at times brilliant results reported by me during the past three years. Fully realizing the destructive action of mercury upon tubercle bacilli, but groping in the darkness of empiricism, I discarded for a time my first dosage, and commenced giving small and very slowly increasing doses, thereby, as I see now, only to produce in these patients a strain of parasites immune to the parasitotropic action of the drug. Then I went back to large initial doses, but not sufficiently large to produce the parasitotropic action of the drug with any degree of certainty or regularity.

The most efficient initial dose will be that which will just fall short of producing mercurialism, after which, depending to a great extent, I believe, upon whether the disease is a chronic or an acute infection, a few succeeding doses may or may not be required to complete the cure. Several months ago I carefully increased the initial dose of mercuric succinimide, and found that 0.091 gram (1 2/5 grains) is the most satisfactory dose for the average adult male patient; it is probable that this dose will at times produce mercurialism, but it can be used with perfect safety, and in all probability will reduce the number of, if not the necessity for, succeeding injections in most, if not all, diseases where it is indicated.

If mercury is the chemical affinity for one vegetable organism it seems logical that the same chemical reaction will take place when one of these organisms is substituted for another, they all having about the same chemical composition; I have therefore developed the following theory:

For Every Vegetable Organism Mercury Is the Chemical Affinity.—This may be expressed by chemical formula as follows: (Vegetable antigen + Hg) + antibody + complement = complement fixation (cure).

With the above in view, on May 16, 1911, when my colleague, Passed Assistant Surgeon W. G. Farwell, U. S. Navy, reported that a case of bronchopneumonia then under treatment was worse, I made known my theory, and with his support gave the patient an injection of 0.019 gram (3/10 grain) at 3:20 P.M. with the most brilliant results. With this encouragement we have since treated twenty-four additional cases, embracing nine distinct diseases of vegetable parasitic origin, and one in which the organism is unknown, with the results noted below. As the case of acute miliary tuberculosis referred to in the opening of this paper was the first case of any disease in which I have injected

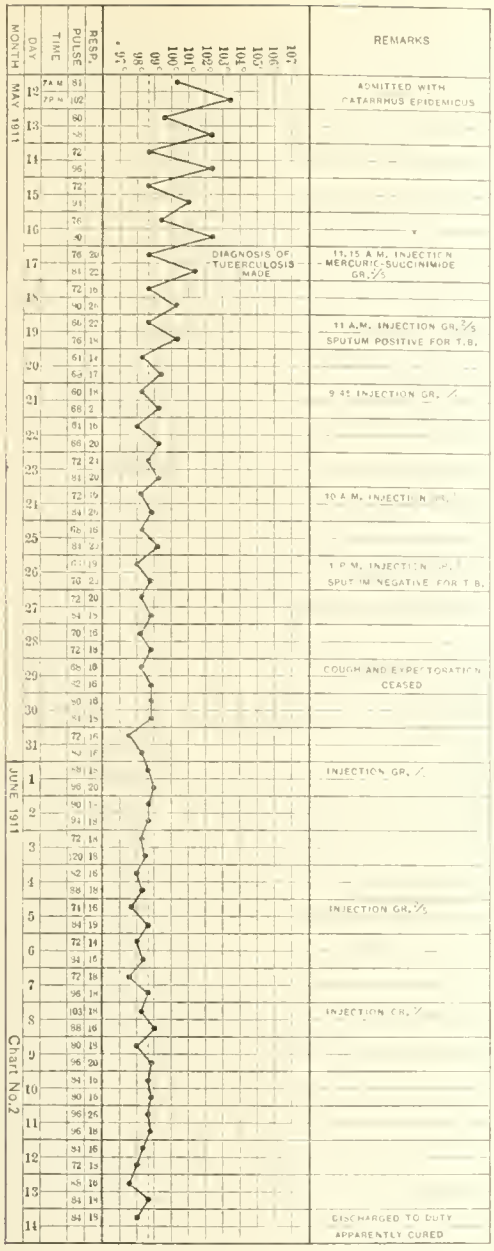
the succinimide of mercury with the definite idea that it was the chemical affinity of the causative organism, and as the subsequent history of the case is of peculiar interest, I include it in this series, briefly reviewing the case as reported, and following up the case after his discharge to duty apparently cured.

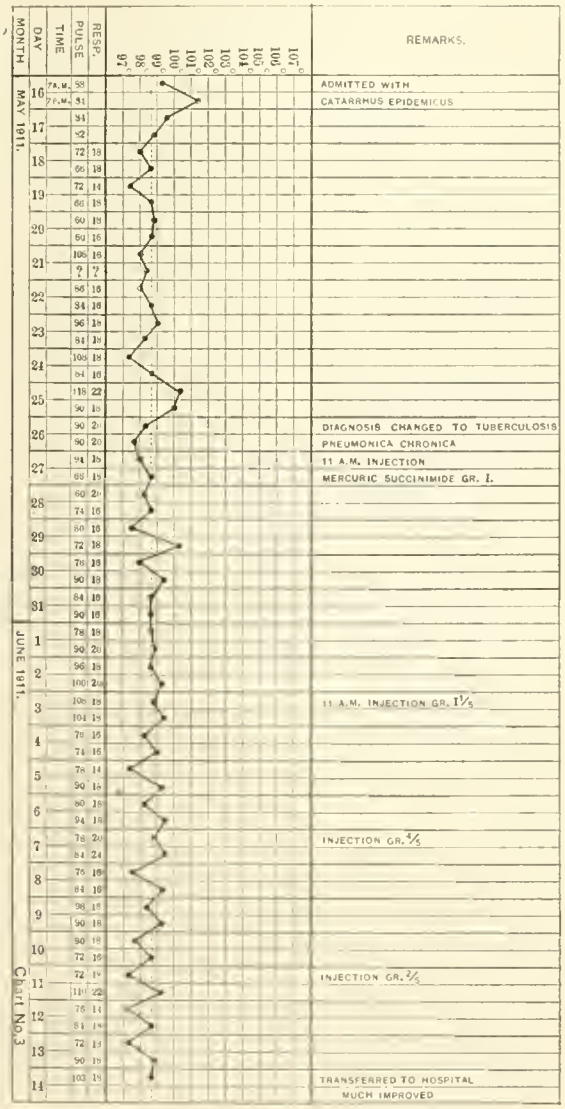
Tuberculosis, Three Cases.

Case I.—Acute miliary tuberculosis of pulmonary type. Patient 25 years old, always in good health previously. Athlete of exceptional strength and ability. Admitted to sick list November 4, 1910, with acute severe illness of sudden onset, both lungs involved, quickly extending through entire area; left pleura developed fluid exudate November 11; on the 12th, 850 cc. serosanguinous exudate was removed by aspiration. Profuse night sweats. November 23, tubercles on left choroid. December 3, sputum positive for tubercle bacilli. December 16, von Pirquet test positive. Chart No. 1 shows the acuteness and severity of the infection, the dose and time of each injection, and the marked parasitotropic and curative action of the succinimide of mercury (chemical affinity) in this case. The day prior to his admission this patient weighed 165 pounds stripped; on November 14, or the tenth day of his illness, about 130 pounds; when discharged to duty, December 26, 148 pounds; on January 12, 1911, the date of my paper, he weighed 163 pounds stripped. His history subsequent to his discharge to duty is of peculiar interest. From January 12, 1911, until May 22, 1911, I saw the man almost daily. During this time his pulse ranged from 72 to 76, and temperature from 98° to 98.6°. He presented no objective or subjective symptoms of disease, performed his duty perfectly, practised with the baseball team, went in swimming, and exercised freely and at will; repeated examinations of the lungs were negative. On May 21, 1911, at 9:30 A.M., he was apparently in excellent health; pulse was 72, respirations 18, and temperature 98.2°. He was weighed and tipped the scales at 172 pounds stripped, or four pounds more than he had ever weighed before. At 7:30 P.M. of that date he reported at sick call, saying he felt tired; his temperature was 100°. He was placed in bed, given magnesium sulphate, 30 grams, and quinine and phenacetin, 0.324 gram. The following morning he complained of severe pain and tenderness over the appendix; the right rectus muscle was extremely rigid, and a diagnosis of appendicitis was made, the lungs were examined and found to be negative. He was transferred to the U. S. Naval Hospital, Chelsea, Mass., where the diagnosis was confirmed and an operation was performed. On opening the peritoneum a serous exudate escaped; tubercles were discovered on the peritoneum, including that of the appendix; the omentum was thickened. The appendix was removed and the wound closed, and the diagnosis changed to acute miliary tuberculosis. The patient died some six days following the operation, and I am indebted to Surgeon F. M. Furlong, U. S. Navy, for the report of the autopsy as follows: Both lungs showed healed tubercles, indicating the active lesion I reported him as having during his first attack; in the left pleura were healed lesions such as I described in the previous paper; in addition, the right pleura presented old adhesions representing an involvement which escaped me during the primary attack; in addition to these healed lesions a new



tuberculous consolidation, with a cavity about the size of a chestnut was found in the immediate apex of the right lung anteriorly. Below the diaphragm all the abdominal organs and tissues were involved, new miliary tubercles being found in the liver, spleen, both kidneys, and the peritoneum, and a few tuberculous ulcers in the mucosa of the intestines. No old lesions were found below the diaphragm. Thus the picture is presented in this one patient of a primary attack of acute miliary tuberculosis of pulmonary type ending in recovery with apparent cure, this apparent cure lasting five months, at the end of which time the man weighed four pounds more than at any previous time of his life, when he was suddenly seized with what proved to be a miliary tuberculosis of abdominal type from which he died. I have heard that many of the profession regarded this case as described by me in the primary attack as one of bronchopneumonia. The subsequent history and postmortem findings confirm beyond question the correctness of my diagnosis, and that he made such a brilliant recovery and apparent cure firmly established the value of mercury in the treatment of tuberculosis. Had I continued the administration of mercury in interrupted courses, giving four or five large injections, at varying intervals of from four to eight weeks I think it probable that the second attack would not have occurred. If the primary attack in this patient was a bronchopneumonia then the curative action of mercury in these cases must be considered.

Case II.—A man, 33 years old, was admitted May 12, 1911, with the diagnosis of catarrhus epidemicus. He was given the usual treatment for this type of infection until May 17, when the diagnosis was changed to tuberculosis. The local lesion was an infiltration of the right upper lobe. The sputum was positive for tubercle bacilli on May 19. The first injection of mercuric succinimide, 0.025 gram (2/5 grain) was followed by immediate improvement. Following the fifth injection the temperature, pulse, and respiration became practically normal and the sputum negative for tubercle bacilli. (See Chart No. 2.) The cough and expectoration entirely ceased on May 29. Three additional injections were given, and the man was restored to duty on June 14, apparently cured, since which time he has had no objective or subjective symptoms of disease and has performed his full duties on this ship without effort. Examination this date (October 11, 1911), four months after discharge to duty, during which time he has not received treatment, shows no objective or subjective symptoms of disease.



Pulse, 74; respiration, 18; temperature, 98.4°; weight, 155 pounds, or 7 pounds heavier than his highest previous weight. I will resume injections in this case at once, commencing with 0.091 gram (1 2/5 grains); on the fourth day following, 0.052 gram (4/5 grain); four days later, 0.026 gram (2/5 grain), etc., until five injections in decreasing doses have been given, when in order not to render the possible remaining latent organisms immune to the chemical affinity they will be discontinued for the time being, at least. Chart No. 2 presents the course of disease, together with treatment; the temperature and pulse curves show the marked immediate curative (parasitotropic) action of mercuric succinimide (chemical affinity) in these cases.

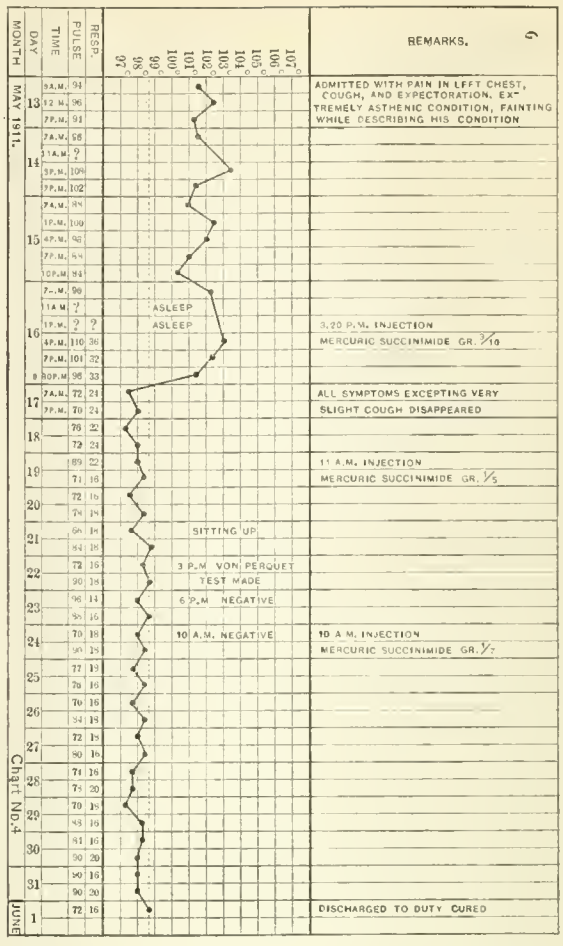
Case III.—A man, aged 21 years, with a particularly bad family history, was admitted May 16, 1911, as with a diagnosis of epidemic catarrh, which diagnosis was changed to tuberculosis May 26, when there were physical signs of infiltration in the upper halves of both lungs. There were severe cough, profuse sanguinopurulent expectoration, negative for tubercle bacilli, and the patient was extremely weak. There was pain following first injection, on May 27, of 0.065 gram (1 grain). This made him refuse further injections until June 3, when 0.078 gram (1 1/5 grains) was given, with slight improvement after the first injection, becoming marked after the second injection, with diminution in cough and expectoration, and marked increase in the appetite and strength. Following the fourth injection his symptoms were still better, but the ship arriving at Boston he was transferred to the Naval Hospital at that place, since which time I have not been informed as to his condition. Chart No. 3 shows the course of the disease, the treatment, etc., while on this ship.

Bronchopneumonia, One Case.

Case IV.—Boilermaker, 39 years old. Diagnosis; Bronchopneumonia. Reported at sick call May 13, 1911, at 8:15 A.M. Complaint: Extreme weakness, pain in left chest, cough, and expectoration. Physical examination showed scattered areas of consolidation in the left upper lobe. By the 16th this condition had spread throughout the entire area of both lungs, with profuse and intermittently rusty sputum containing pneumococci and staphylococci, the former being very numerous. Von Pirquet test was negative. Sputum negative for tubercle bacilli. At 3 P.M., May 16, he was reported by Dr. Farwell as being much worse, and his transfer to the hospital was suggested and considered. At this time I presented my theory, and with Dr. Farwell's support, at 3:20 P. M., I injected 0.019 gram (3/10 grain) of mercuric succinimide; at 4:30 P.M., crisis; 4 A.M., May 17 (12 hours after injection), temperature was 97.4°; pulse, 70; respirations, 24. Convalescence was established, and all the symptoms disappeared. Discharged to duty June 1, 1911. Absolute cure followed the first injection. Chart No. 4 shows course of disease and treatment. Attention is invited to the fact that in this case temperature fell by crisis, while in the case of acute miliary tuberculosis the temperature fell by lysis.

Typhoid Fever, Three Cases.

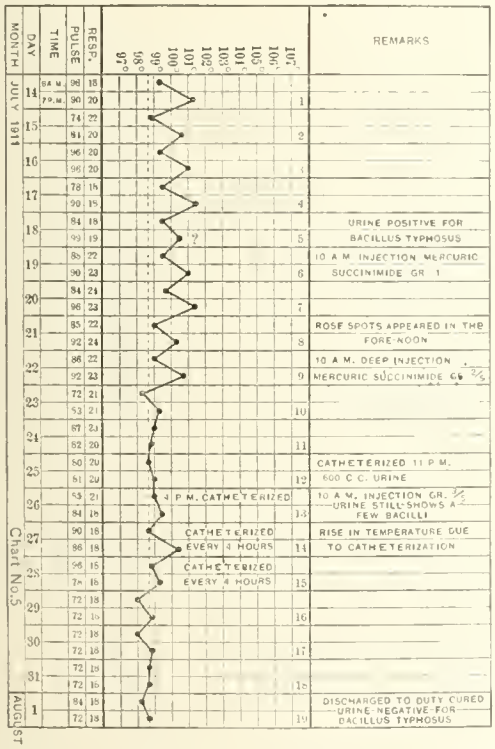
Case V.—Patient 23 years old. Admitted July 14, 1911, with tentative diagnosis of malaria. Blood negative for malarial parasites and on the



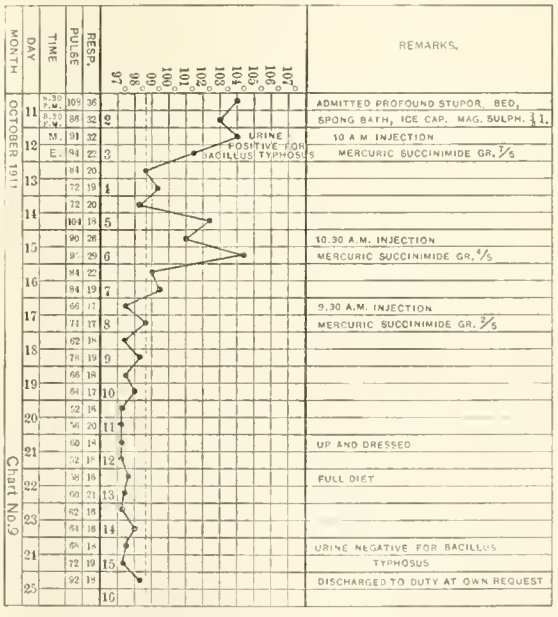
morning of the 18th, Assistant Surgeon Turner of the Maine Naval Militia, then on board; Passed Assistant Surgeon W. G. Farwell, U. S. Navy, and myself in consultation unanimously agreed upon a diagnosis of typhoid fever based on the clinical symptoms, which, with the exception of the rash, which had not yet appeared, were typical of a mild case. I suggested to Dr. Farwell that he examine tht urine for *Bacillus typhosus*. At 2 P.M. he reported these organisms in large numbers. They were seen and recognized as such by Dr. Turner and myself. By this time the patient had lost considerable weight. At 10 A.M., July 19, 0.065 gram (1 grain) of mercuric succinimide was injected. The following morning the patient felt better; by the next morning he was markedly improved; diarrhea had ceased, headache had disappeared, and the tongue was cleaner. On this day (July 21) rose spots appeared upon the abdomen. On July 22, 0.026 gram (2/5 grain) of mercuric succinimide was injected; on the 23d, four days after the first injection, and the day following the second, it being the tenth day of the disease, the temperature and pulse fell to normal, convalescence was established, and with the exception of the retention of urine which occurred on July 25 this was uneventful, resulting in complete recovery on August 1, patient having been sick just nineteen days. Chart No. 5 shows the course of the disease, the number of injections, and dosage given. It is to be noted that on July 26 the number of *Bacillus typhosi* in the urine were markedly decreased, and that on August 1 they had disappeared.

Case VI.—Patient 17 years of age. Enlisted May 16, 1911, and was sent to the U. S. Naval

Training Station, Newport, R. I.; was transferred to this ship, reporting aboard on October 5, 1911, at which time I made a physical examination and found him to be in good health. His health record shows that he had chicken pox and diphtheria before enlistment; no illness since enlistment until present attack. On October 10 he was taken sick but did not report for treatment; at 6:15 P. M., October 11, a chief petty officer brought him to the sick bay; his temperature was 104°, pulse 108, and respirations 36, and he was in a profound stupor; after considerable effort he was aroused sufficiently to say that his "head hurt." Examination of the chest gave the physical signs of a slight bronchitis, the heart and abdomen were apparently normal. He was placed in bed, and given a sponge bath, and ice cap. Thirty grams (1 ounce) magnesium sulphate were administered. The following morning there was but little change, the spleen was slightly enlarged, and the tongue coated; stools pea-soup in character, with scant high-colored urine. Blood was negative for malarial parasites, and the white count 15,000. A tentative diagnosis of typhoid fever was made, and at 10:00 A. M. a deep muscular injection of 0.091 gram (1 2/5 grains) of mercuric succinimide was given. The urine was centrifuged for twenty minutes, and a hanging drop from the



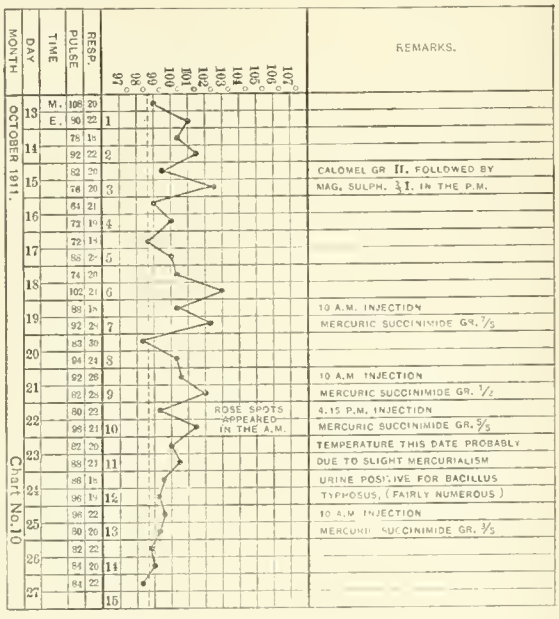
lower portion examined and found positive for *Bacillus typhosus*. By 5:00 P. M. the temperature had fallen to 101° and the stupor was clearing up. At 8:00 A. M., October 13, the temperature was normal. Pulse was 84 and respiration 20; the patient stated that he felt perfectly well; at 11:00 P. M. the temperature was 98°, pulse 72, and respiration 18; I thought that the parasitotropic action of the mercuric succinimide (chemical affinity) had been complete. At 8:00 A. M., October 14, this belief was strengthened by the facts that the temperature was 98.2°, pulse 72, and respiration 20, and that the urine was negative for *Bacillus typhosus*. The temperature slowly rose during the day (see chart) but, firm in the belief that all the organisms were destroyed, I permitted myself to think that the rise in temperature was due to an endotoxemia, and therefore did not give a second injection at this time. However on October 15, the 8:00 A. M. temperature being 101°, pulse 90, and respiration 26, it was evident that some of the infecting organisms had escaped death, had multiplied, and had relighted the pathological condition with resultant toxemia; at 10:30 A. M. I injected 0.52 gram (4/5 grain) of mercuric succinimide, and by the following morning, October 16, the temperature had fallen to 99°, and at 10:00 P. M. the temperature was 98.4°, pulse 70, and respiration 20. The urine this day showed a few actively motile bacilli. Convalescence was established at this point, the 7th day of the disease, and the 5th day after the first injection. From the history of the case and the temperature curve it is evident that this result could have been accomplished in two days' less time had I given the second injection on October 14, when the temperature began to rise, instead of waiting until the 15th. To be on the safe side I gave a third injection on October 17 of 0.026 gram (2/5 grain). On the 18th the white count was 6,300 and in the urine a few sluggish bacilli having a tendency to clump were found. On the 20th the urine contained a very few bacilli which were almost totally lacking in motility. On the 21st the patient was up, dressed, and about the ship, and on the 22nd he resumed full diet. October 24 he was practically ready for duty, the urine was negative for *Bacillus typhosus*, but he will be retained on the sick list a few days longer. Chart No. 9 shows the course of the disease, and



the temperature curve well demonstrates the marked parasitotropic action of mercuric succinimide by the critical falls in temperature following each of the injections on October 12 and 15 respectively.

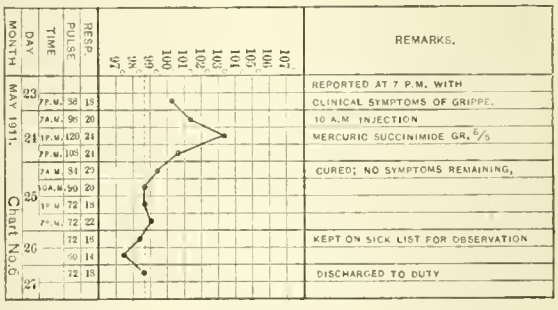
CASE VII.—Patient 20 years of age, admitted to the sick list October 13, 1911, at 8:15 A. M. Complaint, pain in the small of the back, temperature 99°, condition thought to be myalgia of lumbar muscles, salol prescribed; later in the day felt worse and was put in bed; the evening temperature was 101.2°, and pulse 80. The following morning, patient being constipated, he was given magnesium sulphate, 30 grams (1 ounce), without result; the dose was repeated that evening with no results. On the morning of the 15th he complained of severe

pain in the pit of the stomach; abdomen was carefully examined; it was flaccid and no mass could be detected. Calomel, 0.130 gram (2 grains), was given in broken doses followed by magnesium sulphate. This was followed by a free movement of the



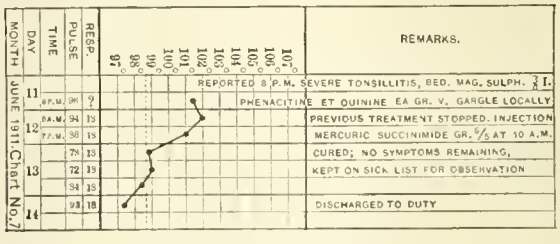
bowels with instant relief. During the 16th the bowels did not move, and the case was considered to be one of obstinate constipation. Two compound cathartic pills were given at 8:00 P. M. On the 17th constipation continued, and the patient again had severe pain in the abdomen, which was examined with negative results. A saturated solution of magnesium sulphate 4 c.c. (1 dram) every half hour; there was a small movement of bowels; at 7:30 P. M. 2 compound cathartic pills were given with relief. October 18 the evening temperature rose to 103°, pulse 102, respiration 21. Syphilis being excluded, it was thought an infection of vegetable parasitic origin confronted us, and the following morning, October 19, an injection of mercuric succinide 0.091 gram (1 2/5 grains) was given, followed by improvement; on the 21st 0.032 gram (½ grain) was injected; on the 22nd rose spots appeared on the abdomen and a positive diagnosis of typhoid fever was made; in the afternoon of that date the temperature showed an inclination to shoot upward, the patient became slightly hysterical, carphologia and subsultus tendinum developed, and at 4:15 P. M. mercuric succinimide, 0.065 gram (1 grain), was injected; between 9 A.M. and 4 P.M. of the 23d the patient had ten copious watery stools, but no abdominal pain. This injection was followed by immediate improvement, all nervous symptoms disappeared, the patient sleeping naturally and soundly from 8:00 A. M. to 1:00 P. M. The raised morning temperature on this date is attributed to the slight mercurialism. The ship being under way at sea prevented examination of the urine for *Bacillus typhosus*. On the 24th urine was positive for *Bacillus typhosus*; the patient's improvement continued. On October 26 the temperature fell to normal and convalescence was established—this being the 14th day of the disease, and the 8th day following the first injection. Chart No. 10 shows the course of disease, treatment, etc.

Comparing these last two cases it will be seen that the earlier in the disease the injection is given the better and more prompt the results. By looking at the temperature curve of the last case it will be noticed that 0.130 gram (2 grains) of calomel, prescribed by Dr. Farwell on October 15 in broken doses, 0.016 gram (¼ grain) every hour, for the purpose of moving the bowels, very nearly aborted the disease on the 16th, emphasizing the advantages of beginning treatment at the earliest possible moment. It seems probable that in diseases in which the causative organism is a rapidly growing one a shorter interval between injections will produce better and more rapid results than the interval mentioned previously in this paper, and in the future in these cases I will give the second injection (4/5 to 1 grain) twenty-four hours after the first; this procedure may also produce better results when treating diseases caused by the more slowly growing organisms such as tubercle bacilli. When treating typhoid fever and the initial injection is not given until the latter part of the second week or later, 0.091 (1 2/5 grains) sometimes produces mercurialism (with violent peristalsis. The initial injection should not be more than 0.065 gram (5/5 grain) to safeguard the patient against perforation. Sometimes the only symptom of mercurialism is a rise of temperature. This is easily mistaken for a symptom of toxemia, due to the activity of the specific organism, and should this mistake be made and an injection be given, it should only serve to further mislead the physician, unless the more classical symptoms of mercurialism presented themselves.



Catarrhus Epidemicus, Five Cases.

Cases VIII-XVII.—These were all cases typical of an infection of this nature, which need not be described. The preponderating organism in the sputum of all these cases was the staphylococcus: four cases were cured by one injection in twenty-four hours, the fifth required two injections. Chart No. 6 well represents these cases.



Tonsillitis, Acute Follicular, Ten Cases.

Cases XVIII-XXVI.—Nine cases were cured in from twenty-four to thirty hours with one injection. One case was cured in 48 hours with one injection, no local or other systemic treatment being given any of the patients. Chart No. 7 is typical of these cases.

Cystitis, One Case.

Case XXVII.—This was of staphylococcic origin, in which the urine was flooded with pus for four

days, during which time the patient was given urotropin, 0.648 gram (10 grains), every three hours, with increasing symptoms. On the fifth day 0.065 gram (1 grain) of mercuric succinimide was injected; in twenty-four hours pus had disappeared from the urine, the infecting organisms were markedly reduced in numbers, and all other symptoms had cleared up. In forty-eight hours the urine was negative for staphylococci.

Otitis Mediachronic, One Case.

Case XXVIII.—This patient had suffered off and on for several years with a more or less severe inflammation of the middle ears. It had been quiescent for about six months, when the condition suddenly relighted, giving rise to the typical symptoms of such an inflammatory process. He received local treatment for a month, at the end of which time he was worse. On September 5, 1911, 0.078 gram (1/5 grain) of mercuric succinimide was injected, with some improvement; on the 10th, 0.052 gram (4/5 grain) was injected, followed by marked improvement; pain almost entirely ceased, as well as did the purulent discharge; the patient was given a third injection and transferred to the hospital for further treatment, much improved. (See Chart No. 8.)

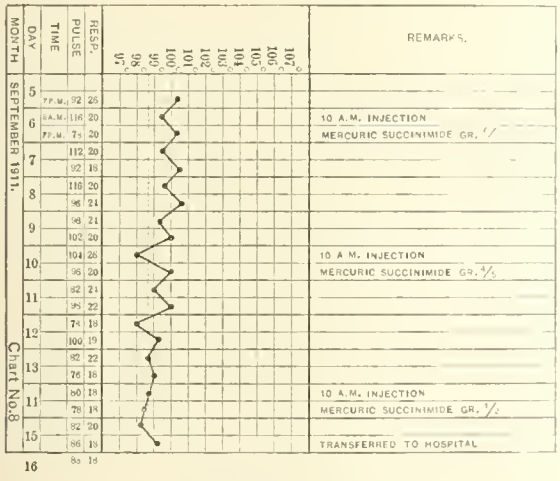


Chart No. 8

Cellulitis, One Case.

Case XXIX.—The patient was admitted October 10, 1911; the middle, ring, and little fingers and the dorsum of the outer side of the left hand were swollen, boggy, painful, tender, red, and hot; diagnosis, cellulitis. Patient's hand placed in a protective dressing and worn in a sling. Injection 0.078 gram (1 1/5 grains) at 10:00 A. M.; October 11, 1911, 8:30 A. M., all symptoms disappeared; discharged to duty.

Furunculosis, Four Cases.

Cases XXX-XXXIII.—Three cases, one injection each of 0.091 gram (1 2/5 grains), followed by rapid disappearance of boils, without new outcroppings. One case, one injection 0.091 gram (2 2/5 grains), disappearance of original crop less rapid, and the appearance of two new boils.

Chancroid, One Case.

Case XXXIV.—Serpiginous chancroidal ulceration at base of penis, treated by usual methods for ten days, growing worse; injection 0.091 gram (1 2/5 grains), no improvement, following three additional injections no improvement.

Conclusions.—The three cases of tuberculosis herein reported strengthen my confidence in the supreme value of mercury in the treatment of this disease, and I believe it to be the chemical affinity of the tubercle bacillus. Whether or not it is also the chemical affinity of all the vegetable parasites remains to be proved or disproved, and I hope that others will use the suggestions contained in this paper to that end. It seems highly improbable that during the short period of nine months of professional work on this ship that I should have an abortive case of miliary tuberculosis (none reported), of chronic pulmonary tuberculosis (none reported), of bronchopneumonia (rare), of typhoid fever, not to mention the remaining diseases reported above, and it would indeed be a marvelous coincidence, even more improbable, that each of these abortions should take place immediately following the administration of a chemical given with the definite idea of curing each of these diseases, unless that chemical possessed the curative properties my theory suggests.

Mercury administered in the large initial doses as I am now using it, continued every fourth day in decreasing doses, is less liable to produce mercurialism than when the initial dose is small and slowly increased during succeeding doses. I have given over 30,000 deep muscular injections of mercury without abscess formation or necrosis, which at any rate should not occur. The only contraindications to this treatment that I know of are organic lesions of the kidneys of non-bacterial origin and asthma. The solution of mercuric succinimide should be made so that 0.260 c.c. (4 minims) of sterile distilled water equals 0.013 gram (1/5 grain) of mercuric succinimide.

U. S. S. Nebraska.

JOHN BROWN, M.D., AND THE BRUNONIAN SYSTEM OF MEDICINE.*

By RICHARD COLE NEWTON, M.D.,

Montclair, N. J.

The subject of this sketch was born in 1735 or 1736, in the village of Lintlaws, or Preston, in the Parish of Buncle, in the County of Berwick, in Scotland. His parents were poor people, but his father appreciated the value of an education sufficiently to send his son to school. The school which young Brown attended was in the village of Dunse, the place where the celebrated Duns Scotus once flourished, a fact of which Brown was apt to speak with pride, calling attention to the circumstance that two such celebrities as himself and the learned philosopher had attended the same school. Brown rose to the highest rank in the school, but, his father having died, he was obliged to relinquish his plan of going to the university and was apprenticed to a weaver. This occupation proving distasteful, he gave it up and went back to the school. He is said to have hired out as a reaper of corn in order to obtain the means for releasing himself from the weaver's occupation and putting himself back in school.

He was a robust young man, and at the age of fifteen walked in one day from Berwick-on-Tweed to Morpeth, a distance of fifty miles, and later on in his career he walked from 4 A. M. one day until 2 A. M. the following day, with only one hour's intermission for dinner.

At school he was regarded as a prodigy. His application was so intense that he was seldom seen

*Read before the Orange Mountain Medical Society, May, 1911.

without a book in his hand. He was at this time of sober habits and exceedingly religious. He was attached to the sect of seceders from the Established Church of Scotland, who were known as Whigs, and so intense was the feeling which these sectarians entertained against the established kirk that young Brown would have considered his salvation in danger if he had read or listened to the "profane discourses of the regular establishment." "He aspired to be a minister of a purer church, of which it was expected that he would be a chosen vessel."

He remained at Dunse at school until he was nearly twenty years of age, working very hard at the humanities, and becoming exceedingly proficient in Latin. About this time out of curiosity he attended a meeting of the synod of the Scotch Established Church which happened to be held near Dunse, and not having been quite so shocked as he ought to have been at the proceedings he stayed and listened to the sermon. This extraordinary performance having been made known to his colleagues of the Scotch Whigs, they were horrified, and called him up in session, where he was rebuked and threatened with extremities unless he recanted and made all due and humble apologies and promises for the future. Brown was obstinate, declined to apologize, and to forestall excommunication withdrew from this communion and joined the Establishment, and, with his usual headlong enthusiasm, became deeply interested in it, attacking vehemently David Hume, whose writings were just then setting all churchmen aghast, and the world at large by the ears.

He now left the grammar school at Dunse and became a private tutor in the family of a neighboring laird, where his superior learning and positive manner led the family to form the habit of referring various disputed points to him for adjudication. On one occasion the laird, having invited some of the nobility and gentry of the surrounding country to dinner, the tutor, as was the custom in that house, repaired to his own apartment after the dessert, leaving the guests to their wine.

Like good Scotchmen of a century ago, when somewhat deeply in their cups, the company engaged in a theological discussion, choosing the comprehensive subject, "The Decrees of Providence." As they did not seem to be making satisfactory headway in their arguments, the host sent a message to the family tutor requesting an expression of his views on the subject. The messenger returned with the surprising information that Mr. Brown considered "The Decrees of Providence very absurd that make so many blockheads lairds."

This incident led to Brown's dismissal from the post of tutor in the family of this particular laird. It shows, moreover, a certain pride of opinion and boldness in expressing his convictions on Brown's part, the certain hallmarks of a born reformer. He then became a student of divinity at the University of Edinburgh, where in the course of time he preached his ordination sermon, which was his first and last sermon, since he failed of ordination for some reason, and giving up the study of theology he returned to the school at Dunse as an usher. In 1759 he competed unsuccessfully for the position of teacher in the High School at Edinburgh. He was then twenty-three or twenty-four years old, and so far had not been especially successful in carrying out his projects to establish himself in life.

Now, however, he turned his thoughts to medicine. It does not appear that he was the seventh son of a seventh son, nor that he had received an "especial" call to practise medicine nor to discover and promulgate a theory. It is more probable that, like the average Chinese physician, he took to medicine because he had failed in his efforts to become a "literate." He repaired again to the University of Edinburgh and became a "grinder." By this suggestive title is meant a person who "grinds out" the young aspirants for the degree of doctor of medicine. Not only did he translate their graduation theses into good Latin, but he tutored them in the same language until they were able to sustain their examinations in this ancient tongue. Not only this, but he would no doubt write the whole or a part of the graduation thesis upon occasion and would help the backward student in other ways to fulfill the requirements of the university.

No doubt some of you who were students in the College of Physicians and Surgeons some years ago will remember the amiable custom, more or less prevalent there, by which for a consideration the aspirant for the doctor's degree could have his graduation thesis written for him by an obliging colleague, and pass it off as his own. In our time, however, the young gentlemen who helped their colleagues to thwart the design of the examiners to exact a well-written thesis from each applicant for a degree kept very quiet about it, and if the professors knew of these performances they said nothing about them, at least so far as I have ever heard. But at the University of Edinburgh the "grinder" was a recognized institution, and while his remuneration seems to have been far less than private quiz masters and thesis writers get in this country, yet his position as a valuable adjunct to the teaching force was recognized. Had we been obliged to hand in graduation theses, written in good, classical Latin, and to sustain our examinations in the same tongue, there would have been abundant use for "grinders" in the old Twenty-third Street Medical School a generation ago, if not since.

Brown now began to study medicine in earnest, but his progress was impeded by the amount of time which he was obliged to give to his tutoring. He, however, soon became proficient as a "grinder." He had now "discovered his strength, and was ambitious of riding in his own carriage as a physician."

He married in 1765, and to help support his family he opened a students' boarding house, which was at first quite successful. But its master was improvident and free handed, and the students soon began not only to live with him but on him. He had become popular among them and was known as a scholar and, unfortunately for his success, also as a jolly good fellow. The intense and emotional piety of his earlier years and his interest in theological questions seem to have subsided, and his attention was largely directed toward having a good time. He paid court at the shrine of Bacchus, surrounding himself with bodies of students and sharing in their revels as well as their serious studies. Finally to make his hold upon them more secure he founded in 1784 a sort of free masons' lodge, which he called the Lodge of the Roman Eagle. He turned the ritual into Latin, which language by this time he spoke as fluently as he did English.

His teaching from the lecturer's chair was, to say the least of it, eccentric. Sometimes he compared his discoveries with those of Newton, to his

own advantage. At other times he grew weary, and the enthusiasm of his young audiences waned with his own. Under such circumstances, in accordance with his doctrine that his natural excitability required to be roused by different stimuli, he would place on one side of the lecture table a bottle of whisky and a phial of laudanum on the other. He would mix forty or fifty drops of laudanum in a glass of whisky, take the draught off at the opening of the lecture, and repeat the dose four or five times during the discourse, working himself up to a frenzy by the time of the peroration.

However, I am anticipating. His proficiency as a scholar had attracted Cullen's attention. Cullen was then at the height of his fame, and was perhaps the leading clinician in the world. He befriended Brown and finally adopted him as his Latin secretary and tutor to his children. About 1765 Brown applied for the position of professor of the theory of medicine, then vacant in the University of Edinburgh, and relied upon Cullen to obtain the post for him. He was unsuccessful in his ambition, and blamed Cullen for his failure. The enmity between them thus started gradually increased, and Brown never forgave his former friend and benefactor for his alleged treachery.

This animosity toward Cullen had much to do with the elaboration of Brown's theory of practice which was largely aimed at the all-prevalent practice of phlebotomy, which Cullen also employed assiduously. With the fate that attends reformers generally Brown finally made himself so unpopular with the professors at the Edinburgh University that, as he alleged, he was obliged to go to St. Andrews' University for his degree as doctor of medicine.

At the risk of making my paper too long I am constrained to quote the following extract from the minutes of the Senatus Academicus of the University of St. Andrews' of date September 21, 1779: "The professor of medicine represented to the meeting of the university that one John Broun was in town, desiring the degree of Doctor of Medicine. That Dr. Flint had examined him in the presence of Mr. Cook, and presented to him the usual trials to be delivered before this meeting, which trials having been revised and approven of by the examinators, Mr. Broun was called in and delivered the said trials to the satisfaction of the university. They accordingly unanimously agreed to confer the Degree of Medicine on him, and ordered his diploma accordingly."

He was unquestionably a learned man, and many have maintained that he was truly a man of genius, although he seems to us in this practical age more like a hard-drinking pedagogue than a master of the healing art, or a scientific physician.

Once when he was afflicted with gout "he partook freely of alcohol before dinner and then called six of his pupils to join him at dinner in order to demonstrate that whereas before he had entered into any degree of intoxication he could not put his inflamed foot to the ground, and could only walk on his sound limb, assisted by a crutch, he could after some intoxication use his affected leg in the most perfect manner. Greatly troubled with gout, he tried in the year 1775 to cure himself by abstinence, and for a time he succeeded. But as the gout returned, and as the practice (of abstinence) did not fit in with his system, he went back to the bottle and stuck to it to the end."
